uggest that without external assistance the typical growth rate of underdeveloped countries would be about 3.4 per cent or less than 1 per cent per capita.

2. *Investment-Limited Growth.* Our hypothesis of an economy with limited flexibility suggests the use of a programming model⁹ in which growth proceeds at the highest rate permitted by the most limiting factor. We assume to start with that the balance of payments does not become the limiting factor. A process by which self-sustaining growth¹⁰ can be attained by using aid to fill the temporary gap between investment ability and saving ability can be derived from the following description of the economic structure:

Definitions:

$$V_t = S_t + C_t,$$

$$S_t = I_t - F_t,$$

Capacity Limit

$$V_t \leq V_0 + \frac{1}{k} \sum_{T=0}^{T=t-1} I_T \quad \text{where} \quad k = \frac{I_{t-1}}{V_t - V_{t-1}},$$

Ability to Invest

$$I_t \leq (1 + \beta)I_{t-1},$$

Saving Limit

$$S_t \leq \bar{S} = S_0 + \alpha'(V_t - V_0),$$

Target Growth Rate

$$V_t \leq (1 + \bar{r})V_{t-1}.$$

The *capacity limit* (3) is based on the Harrod-Domar assumption that specified amount of investment is needed to increase output. The assumption of a linear capital-output function is a matter of convenience. A similar formulation can be derived from more general production functions of the Cobb-Douglas type if there are not significant changes in the relative costs of labor and capital. Since in most cases the period of transition is one in which the total supply of labor is not a significant limitation, it is plausible to approximate the aggregate production function in this way.¹¹

A more complete statement of this model in linear programming form, given in Chenery and MacEwan [7], considers the implications of the present analysis for the optimal planning development.

⁹ This concept will be defined as growth at a given rate with capital inflow limited to a specified ratio to GNP which can be sustained without concessional financing.

The introduction of a nonlinear relation between capital and output would not materially affect the conclusions of our analysis. Intercountry regression analyses suggest that there is a

The *limit on the ability to invest* (4) is introduced to reflect the widely held view that absorptive capacity for additional investment in any period is limited by the supply of complementary inputs, which can only be increased as a result of the development process. We refer to the parameter β as the "skill limit," reflecting the skill formation required of managers, skilled labor, and civil servants in order to increase productive investment.¹² The highest observed value for the skill limit over any recent five-year period is about 20 per cent per year, but few countries have sustained a growth of investment of over 10 per cent for as long as ten years.

The *saving limit* (5) is designed to include not only the marginal propensity to save but the government's ability to increase total saving by changes in the tax structure and by other policies. For this reason, we make the saving limit a function of total GNP (and hence of time) rather than of per capita income.¹³

The *target growth rate* (6) reflects the almost universal practice in developing countries of summing up the principal goal of development in a given rate of increase in GNP. In the present context, it also reflects the fact that foreign assistance is limited and is unlikely to be available to finance growth rates much above 6-7 per cent even if they were attainable. Since the average terms on external loans are based largely on the country's future economic prospects, this puts a limit on the total amount which it can afford to borrow. For all these reasons, either a target growth rate or some other reflection of the fact that investment cannot indefinitely exceed saving must be included in the model.¹⁴

To complete the system, we need some minimal assumptions as to the objectives of the recipient country and the conditions under which aid is provided. We assume that aid is sufficiently limited—or expensive—to make the recipient unwilling or unable to increase aid merely to increase consumption without also securing some rise in GNP. Second, we assume that the country tries to maximize consumption until the target

reduction in the capital-output ratio at higher growth rates but little relation to per capita income. Efforts to estimate more general production functions from time series in underdeveloped countries have been quite inconclusive because of the limited data available.

¹² In the original model for Israel [6], the skill limit was associated with labor only, but in the more typical underdeveloped country the managerial aspect is at least as important.

¹³ Fei and Paauw [9] have recently utilized a similar model to analyze aid requirements for the case in which investment resources provide the limit to growth (our Phase II). They have adapted the Rosenstein-Rodan model [18] by assuming that per capita saving is a constant fraction of the increment in per capita income. There has been no empirical test of the relative merits of this alternative specification of the savings function compared to ours, but they yield similar results when the rates of growth of per capita income and population do not vary greatly.

¹⁴ Alternative formulations are discussed in Section I.C.

growth rate is attained. These assumptions lead to a determinate pattern of growth whose welfare implications will be examined below.

The model of investment-limited growth contains six restrictions and five variables. Under the assumptions made, there is no incentive to build excess capacity or to increase aid by reducing saving. Inequalities (3) and (5) therefore become equalities. The increase in GNP will be limited first by the ability to invest and then by the target growth rate if the investment rate reaches the level ($k\bar{r}$) required to sustain it. We shall denote the first period as Phase I, which is described by equations (1) to (5). In Phase II, inequality (6) becomes effective and replaces inequality (4) as a restriction on the system.¹⁵

The growth path and aid requirements over time can be described by solving for V_t and F_t in each phase and determining the point at which the economy passes from Phase I to Phase II.

Phase I is characterized by a constant growth in investment at the annual rate of β and by an accelerating growth rate of GNP. From equations (3) and (4) it can be determined that the increment in investment in each period is a constant ratio (βk) to the increment in GNP. Solving the system for the level of capital inflow, gives:

$$(7) \quad F_t = F_0 + (\beta k - \alpha')(V_t - V_0),$$

where $F_0 = I_0 - S_0$. This equation shows that the increment in external capital ($F_t - F_0$) finances the difference between the increment in investment and the increment in saving. Without increased capital inflow a country having the median values of k and α' (Table 1) would have a growth of investment of about 5 per cent per year. To achieve a growth of investment of 10 per cent would require that nearly half of the increased investment during Phase I be financed by external capital.¹⁶

This formulation can be interpreted in terms of Harrod's original suggestion of different growth rates corresponding to the growth of the labor force (the "natural" rate) and the potential saving limit (the "warranted" rate). We have replaced the natural rate with a skill-determined rate based on the ability to invest. External assistance fills the gap between investment and saving, permitting the higher rate to be reached.

Phase I ends in year m when investment reaches a level adequate to sustain the target rate of growth:

¹⁵ As shown in [7], this result can be derived in more formal terms by maximizing a welfare function having the characteristics indicated subject to the given restrictions. Each phase is then defined by the restrictions which are binding, which have positive shadow prices. This linear programming formulation is quite useful if we replace the assumption of a target growth rate by a more complicated set of limits, but it is unnecessary with the simplified assumptions made here.

¹⁶ With $k = 3.5$ and $\alpha' = .19$, growth of investment at 10 per cent would require $\Delta I = .35 \Delta V$ of which .19 ΔV (54 per cent) would be financed by increased savings and .16 ΔV (46 per cent) by increased capital inflow.

$$(8) \quad I_m = k\bar{r}V_m.$$

Substituting this value for investment in the equations for Phase I gives the value of GNP in the terminal year:

$$(9) \quad V_m = V_0 \frac{(\beta - r_0)}{(\beta - r_m)}.$$

If, for example, investment grows at 10 per cent per year, the hypothetical median country could increase its investment rate from 12 per cent of GNP with no aid to the 21 per cent needed to support a 6 per cent growth target in a period of eleven years.¹⁷

Phase II in our model corresponds to the process of aid and growth discussed by Rosenstein-Rodan [18] [19]. GNP and investment rise at a constant rate with external assistance determined by the difference between $k\bar{r}$ and α_t . Solving the system for the rate of growth yields a modified form of the Harrod-Domar equation:

$$(11) \quad r_t = \frac{\alpha_t + \phi_t}{k},$$

where

$$\alpha_t = (\alpha_0 - \alpha') \frac{V_0}{V_t} + \alpha' \quad \text{and} \quad \phi_t = \frac{F_t}{V_t}.$$

In order for the rate of capital inflow to decline, the marginal saving rate α' must exceed the investment rate $k\bar{r}$ required by the growth target. If this condition is satisfied, the system can be solved for the level of GNP in year p when the saving rate has risen sufficiently to eliminate the capital inflow:

$$(12) \quad V_p = \frac{(\alpha' - \alpha_m)}{(\alpha' - k\bar{r})} V_m.$$

Since α' reflects the total effect of government policies on saving, there is no reason to assume that it will remain constant throughout the period of the transition.¹⁸

3. Trade Limited Growth. The process of growth with a varying inflow

¹⁷ The time to complete Phase I can be determined by solving for m in the following equations:

$$(10) \quad \frac{I_m}{I_0} = (1 + \beta)^m = \frac{\bar{r}}{r_0} \frac{(\beta - r_0)}{(\beta - \bar{r})}$$

where

$$r_0 = I_0/kV_0 \quad \text{and} \quad \bar{r} = r_m.$$

¹⁸ The effects on the transition of plausible variations in the saving rate are illustrated by the Pakistan example in the next section.

of capital requires a continual adjustment in imports and exports to make the trade gap equal the desired gap between investment and saving. We have assumed so far that this adjustment process—whether achieved through the market mechanism or through government controls—does not affect the growth path or the aid requirements. For many of the countries in Phase II, however, this assumption may not be valid.

Although in Phase I the rising capital inflow needed reduces the pressure on the balance of payments, the tapering off of the capital inflow in Phase II requires exports to rise more rapidly than imports. The empirical analysis of Section II suggests that many countries have been unable to bring about this required adjustment in their productive structure. While this situation may have been caused by overvalued exchange rates or other inefficient policies, the resulting trade gap is often "structural" in the sense that it can only be reduced over time without reducing the rate of growth by a redirection of investment and other resources.¹⁹

The trade limit can be incorporated into the preceding analysis in a form quite analogous to the saving-investment limit. We postulate a minimum import level (\bar{M}_t) required to sustain a given level of GNP at time t , which is similar to the capacity requirement of equation (3). This import requirement results from the relatively inelastic demand for a large proportion of the manufactured goods currently imported—particularly intermediate goods and investment goods—arising from the lack of domestic supply and their necessity in production. Actual imports may, of course, exceed this minimum. This requirement may be stated as:

$$(13) \quad M_t \geq \bar{M}_t = \bar{M}_0 + \mu'(V_t - V_0)$$

where the minimum marginal import ratio μ' may be derived as the average of the incremental ratios for different components of demand.²⁰ While the marginal import ratio is probably more subject to policy control than the capital-output or saving ratios, it represents an important structural limitation over planning periods as long as 10–15 years.

The existing economic structure at any moment in time also limits the feasible growth of export earnings. Since export earnings for many primary products are largely determined by demand conditions, a rapid increase in exports typically requires the development of new export products, which is limited by productive capacity as well as organiza-

¹⁹ The nature of the trade limit is discussed further in [5] [6] [15].

²⁰ These estimates have been made for countries such as Israel, Italy, Pakistan, India, and Argentina by use of input-output models in which import substitution is incorporated on a sector basis. The procedure is described in [5] and [6].

tional and institutional factors. The order of magnitude of this limit is indicated in Table 1 by the recent growth rate of exports, whose median value is 5.1 per cent and upper quartile value is 8.0 per cent. The effects of government policies to increase exports are summarized by the parameter ϵ in the following expression for the export limit:²¹

$$(14) \quad E_t = E_0(1 + \epsilon)^t.$$

The *combined trade limit* is expressed by the requirement that the capital inflow be at least large enough to cover the minimum gap (F_t^m) between import requirements and export earnings:

$$(15) \quad F_t \geq F_t^m = \bar{M}_t - E_t.$$

When the capital inflow determined by the saving-investment gap in equation (2) is greater than the minimum trade gap, the two gaps can be equated by having imports in excess of the specified minimum or exports less than the assumed maximum of equation (14). When the minimum trade gap is the larger, however, it controls the rate of growth of GNP and the inflow of capital. In this case, either saving will fall below the saving potential specified by equation (5) or less productive investment will take place. In either case the saving limit ceases to be binding.

Theoretically the trade limit may replace the saving limit as a determinant of the capital inflow in either Phase I or Phase II. Empirically, this is less likely to happen in Phase I, since the rising capital inflow does not usually require exports to increase as fast as imports.²² Once a target growth in GNP is attained, however, exports must rise more rapidly than imports if aid is to be reduced. If the trade limit becomes effective at all, it is therefore more likely to be during Phase II. We shall denote the new set of restrictions which would be binding in this event as Phase III.²³

In *Phase III* inequalities (3), (6), and (15) become equalities, while limits (4) and (5) are redundant. For a given target rate of growth, GNP is determined by equation (6) as in Phase II. The capital inflow is determined by (15) and exceeds that required by the saving gap.²⁴ In order for

²¹ It is probable that ϵ depends on the growth of GNP to some extent, but we have taken account only of the relationship (14) in applying the model.

²² The relative growth rates required depend on the initial ratio of exports to imports.

²³ The three phases described here can follow each other in any order if we allow the structural parameters to change at random over time. With fixed parameters, the commonest sequence (as shown in Section II) is from Phase I to either Phase II or Phase III. We have not tried to trace such a sequence of phases historically except in the Adelman-Chenery model of Greek development [1] and the Chenery-Bruno analysis of Israel [6].

²⁴ When the trade gap determines the capital inflow in Phase I, we will denote the corresponding set of restrictions as Phase IB. This combination does not seem to be of great significance empirically. The more common case in which the ability to invest and the saving limit are controlling will be renamed Phase IA.

the capital inflow to be reduced, either export growth must exceed the target rate for GNP or the marginal import ratio must be substantially less than the initial average. From equations (13) and (14) we derive the following condition for the elimination of the trade gap with constant structural parameters within a given period ($q-j$):

$$(16) \quad \frac{E_j}{M_j} (1 + \epsilon)^{q-j} - \frac{\mu'}{\mu_j} (1 + \bar{r})^{q-j} \geq \left(1 - \frac{\mu'}{\mu_j}\right).$$

Since the parameters ϵ and μ' are more amenable to policy control in the long run than are k and α' , Phase III conditions are less likely to persist throughout the transition than are those of Phase II unless the efforts of the underdeveloped countries to increase their exports are frustrated. For the projections to 1975 that are made in Section II, however, Phase III is of great importance.

4. *Total Requirements for External Capital.* The total capital required under our assumptions to complete the transition to self-sustaining growth can be determined as the sum of the capital requirements for each phase that the economy goes through. In Phases IA and II, external capital is determined by the cumulative difference between investment and savings. In Phases IB²⁵ and III, it is the cumulative difference between import requirements and exports.

The equations for capital inflow in each phase are given in a symmetrical form in Table 2. All variables are expressed as a ratio to the initial level of GNP (V_0). Summing these equations over time and assuming constant parameter values gives the total capital inflow during any period that the economy remains in that phase. These formulas for cumulative capital inflow are used in subsequent comparisons of growth paths and capital requirements.

B. *The Transition in Pakistan*

We can best illustrate the operation of our basic model by applying it to a specific case. Pakistan will be chosen for this purpose because it has actually started from a very low level of income and accelerated its rate of growth through the use of external resources. Unlike the more advanced countries cited earlier, however, Pakistan has only completed the first decade of a process which may take several decades more. The projections which we will make for Pakistan, therefore, illustrate the procedure to be followed for a large number of countries in Section II in calculating the range of future needs for external capital.

For the past eight to ten years Pakistan has been following the sequence envisioned in our Phase I of a rapid expansion in investment,

²⁵ See footnote 24.

saving and external assistance. In 1956²⁶ Pakistan was in the lower quartile of countries with respect to its investment, saving, and growth rates. As shown in Table 3, its performance since then has approximated the upper-quartile values for the main performance measures in our model: absorptive capacity, capital-output ratio, marginal saving rate, and export growth. We take 1962 as the base year for these and all subsequent projections. Base-year values for the variables in the model are given in Table 4, expressed as ratios to 1962 GNP.

The growth process from 1962-75 will be determined from the basic model under two sets of assumptions as to the values of the parameters. The more pessimistic (A) assumptions are based on a conservative interpretation and projection of performance in recent years; the corresponding parameter values are labeled "historical performance" in Table 3. The more optimistic (C) assumptions are derived from the Pakistan Perspective Plan for 1965-85; they are labeled "upper limit" perfor-

^a Projections derived from the base-year data for 1962 and parameter values in Table 3.^b The 1956 and 1962 figures are trend values for the period 1956-62. The latest revision of the Pakistan national accounts [11] gives a similar investment level but higher initial savings and a negative marginal savings rate for the period 1954-55 to 1959-60.^c For 1956 and 1962, potential and actual savings and imports are the same, and the two gaps are identical; from 1963 onward, the larger can be

mance.²⁷ In the case of Pakistan, the upper-limit assumptions are higher than the historical estimate for the growth target, the saving rate, and the growth of exports; the other three parameters already seem optimistic and have been kept unchanged.

Figure 1 and Table 4 show trend values of the variables from 1956 to 1962 and the two sets of projections derived from the model for 1962-75. Although the data before 1960 are not very reliable, it is clear that investment from 1956 to 1964 has grown very rapidly and doubled its share in GNP.²⁸ The rate of output growth has increased from about 2 per cent prior to 1958 to over 4 per cent since 1960.

The two sets of projections give the following sequence of phases:

	(A) Historical Performance	(C) Upper-Limit Performance
Phase I ²⁹	1956-63	1956-67
Phase II	1964-67	1968-73
Phase III	1968-	1974-
End of Transition	After 1985	After 1979
Target Growth Rate	4.5 per cent	6.0 per cent

In case C it takes ten years of steadily rising investment from the 7 per cent level of 1956 to reach the rate of 18 per cent of GNP required by a growth rate of 6 per cent. The capital inflow would reach a maximum of 6 per cent of GNP in 1967; throughout Phase I it would finance about 30 per cent of total investment. If the saving-investment limit were the only constraint on the system, the capital inflow could then be reduced to zero by 1980 if the marginal saving rate of .24 were maintained.³⁰ However, even with the relatively high export projection of 7 per cent per year, the model projects a switch to Phase III in 1974 with a marginal import requirement of .10. There is also a switch to Phase III in case A, even though export growth is assumed higher than the growth of GNP. The same phenomenon occurs in the projections in Table 7 below for the majority of developing countries.

²⁷ The projections in Section II also contain an intermediate set of estimates and growth targets for each country designated as "realistic plan performance." When the country's own plan seems quite optimistic, as in Pakistan, we have taken it as the basis for the "upper limit" estimates.

²⁸ The figures in Table 4 are derived from trends fitted to the time series for each variable and differ somewhat from estimates based on the initial and terminal years of each series. A detailed account of the decade 1955-65 is given in the Pakistan Third Five-Year Plan [11]. The general picture that it gives is similar to our upper-limit projections through 1965 except that both investment and foreign capital inflow are higher in the latter year. The statements in the text are consistent with both sets of estimates.

²⁹ There is considerable evidence that the trade limit was the controlling factor from 1956-59, which would identify this period as Phase IB.

³⁰ This is approximately the assumption of the revised Pakistan Perspective Plan [11] which aims at a 7 per cent growth rate and a termination of aid by 1985.

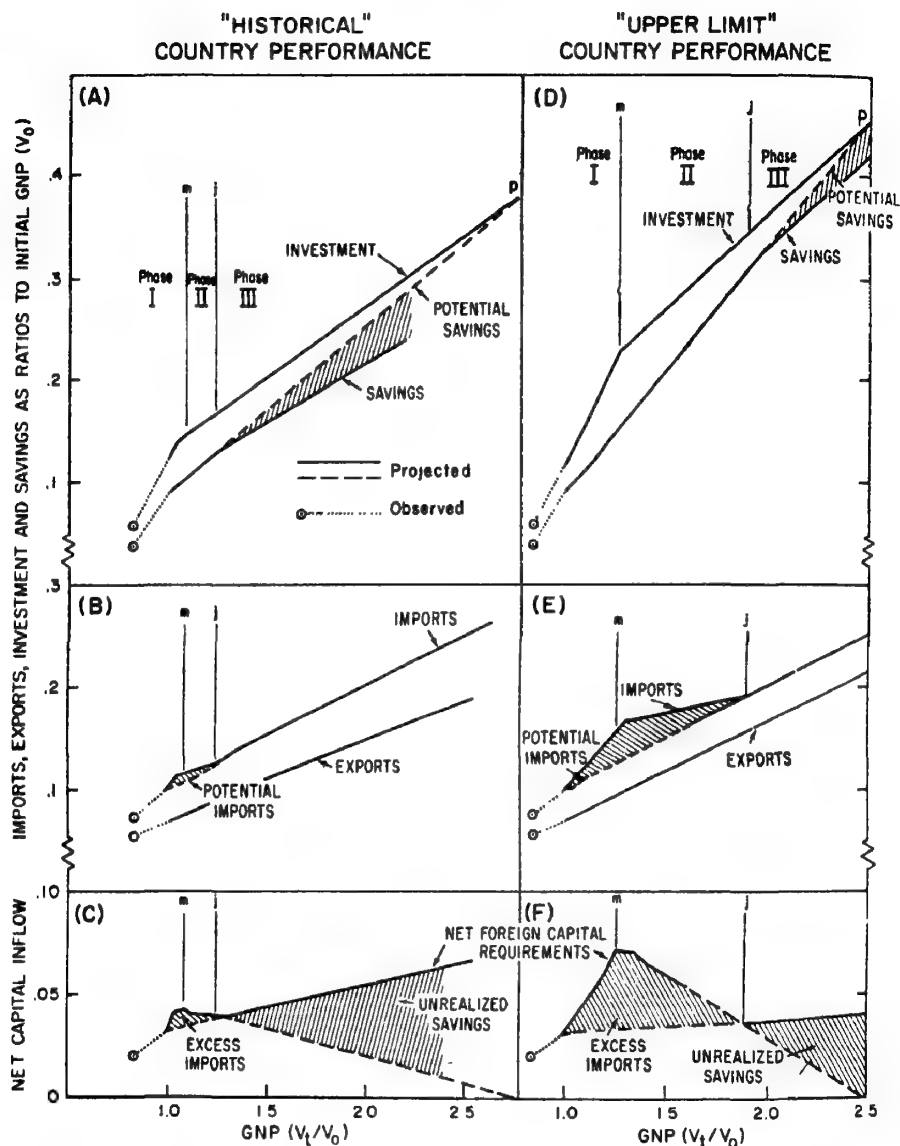

FIGURE 1. ILLUSTRATIVE GROWTH PATHS: PAKISTAN, PAST AND PROJECTED

The importance of the marginal saving rate is demonstrated by a comparison of the two projections. If the balance of payments parameters are subject to sufficient policy control in the longer run (as suggested below), the economy will reach self-sustaining growth at a rate of 4.5 per cent in 1985 under the lower assumption of a 16 per cent marginal saving rate. With a 24 per cent saving rate, a self-sustaining growth

rate of 6 per cent can be attained six years sooner. While more aid is required in the latter case, there is a much larger increment of saving and investment as well.³¹

C. *More Efficient Growth Paths*

The more time that is allowed for an economy to adjust its productive structure to the changing pattern of demand, the less likely it becomes that the rigidities assumed in the basic model will persist. We shall therefore construct a second model which assumes coordinated development policies and a planned adjustment of the trade gap and the saving gap. Actual cases will probably lie somewhere between these extremes.

Under the assumptions of model 1, the amount of external resources needed to fill the larger gap in a given year more than fills the smaller one. As compared to the minimum needs of the economy, there will be a surplus of imports ($M > \bar{M}$) in Phase II or a loss of potential saving, ($S < \bar{S}$) in Phase III. A better coordinated development policy would attempt to reduce the required capital inflow by substituting investment for imports—or vice versa—in order to equate the two gaps *ex ante* over the long run.³²

If we assume efficient resource allocation, the equilibrium exchange rate—reflecting the opportunity cost of earning or saving foreign exchange at the margin—will be a function of the amount of inflow of external resources, F . Under *ceteris paribus* assumptions, a reduction in F normally implies an increase in the value of foreign exchange as marginal activities of import substitution or additional exports are undertaken. Since capital is the only scarce domestic resource in our model, we assume that a higher capital coefficient is needed to reduce the import requirements of model 1 and conversely that a saving in capital will result when imports increase above the minimum level.³³

These assumptions form the basis for model 2, in which an import substitution activity is added to model 1.³⁴ Investment in import substitution I_m requires imported capital goods and a greater amount of capital (b_k) per unit of imports replaced by domestic production. The net

³¹ A generalization of these relationships is given in Section I.D.

³² Given the durability of capital, it may not be efficient to equate the two in the short run, especially when there is a significant degree of disequilibrium to start with.

³³ The efficient reallocation of resources to accord with variations in the capital inflow is analyzed in detail in Chenery [5], which provides the basis for the aggregate formulation given here. We have approximated the diminishing marginal productivity in import substitution by a single incremental ratio.

³⁴ The same argument can be made for export expansion, using the marginal revenue product of additional investment to allow for the inelasticity of export demand. For convenience, we assume only import substitution here.

reduction in import requirements at time t ($M_{m,t}$) is given by:

$$(17) \quad M_{m,t} = \frac{1}{bk} \sum_0^{t-1} I_{m,t} - aI_{m,t},$$

where a is the import content of I_m above the average for the economy and b is greater than 1.

Equation (13) of the basic model will then be replaced by:

$$(13') \quad M_t \geq \bar{M}_0 + \mu'(V_t - V_0) - M_{m,t}.$$

The capacity limit, equation (3), must also be modified to allow for the lower productivity of capital in import substitution.

Model 2 will be used to estimate the minimum capital inflow needed to achieve a given level of GNP, first in the Pakistan example and later in comprehensive projections. For this purpose we assume (1) that total import substitution (positive or negative) is sufficient to eliminate the difference between the two structural gaps over the period 1962-75, and (2) that this type of investment increases linearly throughout the period. Solutions calculated for Pakistan for varying growth targets are shown in Table 5.³⁶ Cumulative values of the two gaps in model 1 and of the single gap in model 2 are plotted in Figure 2.³⁶

Figure 2 shows that at a growth rate of GNP of 5.2 per cent, the cumulative values of the two resource gaps in model 1 are the same and equal to the total requirement for foreign capital in model 2. At lower growth rates, the trade gap predominates in model 1 and the difference between the two curves represents an excess of consumption. In model 2, about a third of this excess is utilized to finance the additional investment needed for import substitution; the remaining two-thirds is eliminated by reducing the capital inflow.³⁷

At growth rates above 5.2 per cent, Phase II predominates in the basic model and the possibilities of reducing the capital inflow through (negative) import substitution are less. On our assumptions, substituting imports for investment would produce a reduction in the dominant

³⁶ We have used a value of b of 1.5, which implies that additional import substitutes would become profitable at an average exchange rate 50 per cent higher than the present effective rate. This value was judged to be the upper limit to the cost of import substitution or increased exports in the amounts needed to reconcile the two gaps. A comparable value was found in the investment programming model for Southern Italy [5]. The additional import content of investment (a) is taken as .25, corresponding to a total import content of .35.

³⁷ For model 1, we have assumed that the total capital inflow would be equal to the larger of the cumulative resource gaps because of the possibilities of adjustment through stock change, variations in imports, building ahead of demand, etc. Taking the larger resource gap on an annual basis would give somewhat higher totals for model 1 in Table 5 and Figure 2.

³⁸ For example, at a growth rate of 4 per cent excess consumption of .59 in model 1 is converted into increased investment of .19 and reduced imports and capital inflow of .40 in model 2. The same proportions hold at other growth rates below 5.2 per cent.

^a Assumes no constraints on growth of investment or GNP. This means that country could invest sufficient capital in each year to attain the GNP growth rate given in line 2. Actual 1962 investment was sufficient for an initial growth rate of about .04.

^b The basis for Model 2 is given in the text. The formulas for calculation are detailed in [8, Annex B].

saving gap of about a third of the difference between the two gaps in model 1.

A more efficient method of reducing the cumulative capital inflow in cases where the saving gap exceeds the trade gap is to accelerate the rate of growth at the beginning of the period instead of maintaining a con-

FIGURE 2. GAP EQUALIZATION THROUGH ADDITIONAL IMPORT SUBSTITUTION (MODEL 2), PAKISTAN, 1962-75

stant growth rate. This has the effect of increasing total saving as well as total imports, but the net reduction in the capital inflow is greater than with model 2.³⁸ The practical scope for raising the growth rate in most countries is limited by absorptive capacity constraints, however.

A more comprehensive analysis of the efficiency of alternative growth patterns would require us to abandon the assumption of a given target growth rate and to determine the growth target and the pattern of capital inflow from the objectives of the economy and the limits to the use of various policy instruments. This has been done in a linear programming analysis of optimal growth patterns in Pakistan [7]. The results confirm our assumption that it is efficient to eliminate the *ex ante* difference between the two resource gaps to the extent feasible. The main features of the growth pattern determined from the basic model also characterize the optimal solutions to the more general planning model.³⁹

D. *The Productivity of External Resources*

The productivity of an increment in external resources supplied to a developing country can be measured by the corresponding increase in consumption or total income which it makes possible. The value of external resources depends on the extent to which they facilitate the fuller use of domestic factors. In our models, it is possible to measure the effect of increasing the supplies of investment funds and foreign exchange, but we have no estimate of the possibilities for raising the skill limits to growth.

Figure 2 provides one measure of the marginal productivity of external resources in Pakistan over the range of growth rates indicated.⁴⁰ Under the assumptions of model 1, the productivity of aid is much higher in Phase III, when the balance of payments is the factor limiting growth. This result is stated in more general terms in the following formulas for the derivative of the terminal year income with respect to the total capital inflow from the equations in Table 2.

³⁸ The theoretical aspects of the variable growth mechanism are more fully explored in [8]. There it is shown that slowing down growth to save on external capital in Phase III is a very inefficient alternative to import substitution. In the present example it results in a loss of \$11 of consumption per dollar of capital inflow saved.

³⁹ The principal differences between model 1 and the linear programming solutions are (1) a continuation of Phase I beyond the point at which the target rate is achieved in order to maximize the benefits of accelerated growth; (2) replacement of Phases II and III by a single regime in which the capital inflow is reduced to zero with the two gaps kept equal by import substitution, as in model 2 above.

⁴⁰ Since Figure 2 is designed to illustrate the effects of import substitution, we have omitted the complicating element of absorptive capacity, which would raise the total capital inflow required for higher growth rates and put an absolute ceiling on the maximum growth achievable of about 6.3 per cent by 1975 in the Pakistan example. Discounting the total capital inflow at 8 per cent would reduce the total value by 30-40 per cent and raise its marginal productivity.

For Phase II:

$$(18) \quad \frac{d(V_{t+1})}{d(\sum F_t^s)} = \frac{1}{k - \alpha' \gamma},$$

For Phase III:

$$(19) \quad \frac{d(V_{t+1})}{d(\sum F_t^m)} = \frac{1}{\mu' \gamma},$$

where

$$\gamma = \left[\frac{t - \frac{1 - (1 + \bar{r})^{-t}}{\bar{r}}}{\bar{r}(t + 1)} \right].$$

Values of γ for relevant time periods and growth rates are:

\bar{r}	Values of γ		
	$t=4$	$t=9$	$t=14$
.03	1.8	4.1	5.9
.05	1.8	3.8	5.5
.07	1.7	3.5	4.9
.10	1.7	3.4	4.4

These formulas give the following values for the increase in terminal year income per dollar of increase in cumulative assistance for Pakistan and for the median parameter values of Table 1 (assuming $\bar{r} = .05$ and $t = 14$).

	Pakistan	Median Values
Productivity in Phase II	.44	.35
Productivity in Phase III	1.14	.91

For periods under 20 years, there is a pronounced tendency for the two productivity curves to have the relative slopes indicated for Pakistan, with Phase II predominating at high rates of growth.⁴¹ As the length of time increases, the productivity of assistance in Phase II rises because of the additional saving generated, while the productivity in Phase III falls. Under the more optimal policies assumed in model 2, there is a single productivity curve with a slope closer to that of Phase II in model 1.⁴²

For long-term development policy, it is more useful to consider the total assistance required to complete the transition to self-sustaining

⁴¹ This result was also obtained by Chenery and Bruno [6] for Israel and by McKinnon [15] for more specialized assumptions. An estimate of the productivity of aid to Greece is given in [1].

⁴² The marginal productivity curve derived from the linear programming model of [7] is similar to that for model 2.

growth in relation to the country's performance. This can be done by varying the parameters for Phase II of model 1 over the range of values observed in Table 1. The results are given graphically in Figure 3, which shows the total undiscounted capital inflow required to produce a self-sustaining growth rate of 5 per cent from the low initial saving rate of 8 per cent of GNP.⁴³

To show the effect on aid requirements of a change from average performance to "good" performance, we have plotted points corresponding to median values of k and α' (point H) and also upper quartile values (point U). Median performance requires a total capital inflow of more than $2\frac{1}{2}$ times the initial GNP and a period of 43 years to complete the transition to self-sustaining growth. Upper-quartile performance requires a capital inflow equal to only a quarter of the initial GNP and a period of eight years to reach self-sustaining growth (if we ignore the absorptive capacity limitation). Between these extremes, we might distinguish as "good performance" combinations of k and α' which accomplish the transition with a total capital inflow of not more than the initial GNP, such as $k=3.2$ and $\alpha'=.20$. These results will be utilized in the discussion of assistance policy in Section III.

II. Prospects for the Transition

The preceding analysis provides a way of thinking about external resources as an element in the development process. Their contribution to growth may be large or small depending on the response of the recipient country. We shall now try to evaluate the recent performance of the less developed countries and assess their possibilities for further growth and their needs for external resources.

Since efforts to accelerate growth through foreign assistance have been concentrated in recent years, our statistical analysis is based on the period 1957-62. Rough estimates of the basic relations in model 1 have been made for 50 countries which account for 90 per cent of the GNP of the underdeveloped world.⁴⁴ Principal attention will be given to 31 of these countries for which the data are judged to be more reliable.⁴⁵ Our interpretation of the results will also utilize more detailed analyses of a dozen of the most important recipients of U. S. assistance.⁴⁶

⁴³ Model 2 can be approximated by Phase II of model 1 by taking a weighted average of the two incremental capital output ratios in model 2. Figure 3 ignores the absorptive capacity limitations, which would tend to raise the time required for the transition.

⁴⁴ Omitting Communist China, Cuba, and N. Korea.

⁴⁵ The only large countries omitted from the 31-country sample are: Ceylon, Ethiopia, Indonesia, South Vietnam, the Sudan, and the United Arab Republic.

⁴⁶ Preliminary results of the more detailed studies are available for Greece [1], Turkey [25], Colombia [24], and Taiwan [12]. Other countries for which more detailed models have been constructed by AID in order to test the "two gap" analysis of aid requirements and performance include India, Pakistan, Argentina, Brazil, Korea, Jordan, Nigeria, and Chile.

FIGURE 3. TOTAL CAPITAL INFLOW REQUIRED TO REACH SELF-SUSTAINING GROWTH
(Assumes 5 per cent GNP growth rate, initial saving/GNP ratio of .08 and Phase II throughout)

A. Evaluation of Current Performance.

The statistical evaluation of current performance is designed to show the extent to which underdeveloped countries have established the structural conditions required to utilize aid effectively in carrying out a transition to self-sustaining growth. It also sheds some light on the validity of our simplified model and provides a basis for subsequent projections of future growth.

For this survey we have adopted a uniform statistical procedure that is applied to all 31 countries. Estimates of the parameters in the basic model are given in Table A-1 below. The main features of the statistical procedure are as follows:

1. All estimates were made from linear trends fitted to time series for the period 1957-62. Marginal saving rates (α'), marginal import rates (μ'), and marginal capital-output ratios (k) were computed directly from these trends.

2. The magnitude of the absorptive capacity parameter (β) is indicated by the highest compound growth of investment for any five-year period in the past decade. The growth of investment (i) observed for 1957-62 is often well below this limit because development has been constrained by other factors.

3. Trend values for 1962 of the investment, saving, and import ratios to GNP are computed as a basis for future projections.

The estimates in Table A-1 will first be used to determine the extent to which recent performance satisfies the criteria for a successful transition to self-sustaining growth. While six years is too short a period to establish reliable estimates for any single country, a comparative assessment for the whole group of countries is quite suggestive.

We have proposed three sets of criteria in Section I to measure progress toward a given rate of self-sustaining growth;

- (1) *Investment criteria.* In Phase I, the rate of growth of investment must be greater than the target growth rate ($i > \bar{i}$). Thereafter, the investment rate must be adequate to sustain the target GNP growth rate ($I/V \geq k\bar{i}$).

- (2) *Saving criteria.* The marginal savings rate must be greater than the target investment rate ($\alpha' > k\bar{i}$) unless the average rate of saving is already above this level.

- (3) *Trade criteria.* Either export growth must exceed the growth target for GNP or the marginal import ratio (μ') must be substantially less than the initial average ratio. The complete statement of the trade criterion is given by equation (16).

These criteria have been used to classify the 31 countries into the four main groups shown in Table 6. The classification is based on the saving and trade performance needed to achieve a self-sustaining growth rate of 5 per cent.⁴⁷ As to the investment criteria, all countries except Burma have shown an absorptive capacity for investment of greater than 5 per cent in the recent past, but the five countries indicated by an asterisk do

⁴⁷ The parameters should reflect underlying structural characteristics rather than "realized" values in this historical period. The high marginal import ratios for Chile, Nigeria, and Turkey, for example, may reflect Phase II slackness in the foreign trade constraint. The true structural import ratios may be enough lower to move Chile from Group D to C and Nigeria from B to A. Use of parameters for the period 1953-63 would move Mexico from Group C to A.

* All data derived by fitting time trends to actual points (as estimated in early 1965) for period covered. All data except imports, exports, and reserves expressed in 1962 prices. Imports, exports and reserves expressed in current U. S. dollars.

^b Symbols for column headings are:

βi = compound growth rate of gross investment.

k = incremental capital-output ratio (assuming 1-year lag).

r = compound growth rate of GNP.

I_0 = ratio of gross investment to GNP in 1962 (after time-trend fitting).

Φ_0 = ratio of net foreign capital inflow to GNP in 1962 (after time-trend fitting).

α_0 = ratio of national gross savings to GNP in 1962 (after time-trend fitting).

α' = marginal national savings ratio (change in savings ÷ change in GNP)

* Country numbers correspond to those in Tables A-2 and A-3.

Source: Imports, exports and reserves largely from IMF, *Balance of Payments Yearbook*. Other data from U. N. *Yearbook of National Accounts* and from AID, Statistics and Reports Division.

μ_0 = ratio of gross imports of goods and services to GNP in 1962 (after time-trend fitting).

μ' = marginal import ratio (change in gross imports of goods and services ÷ change in GNP).

ϵ = compound growth rate of exports of goods and services.

ρ' = change in gold and convertible foreign currency reserves, December 1956 to December 1962 ÷ change in GNP, 1957-62. GNP first converted to 1962 U. S. dollars (after time-trend fitting).

TABLE 6—INDICATORS OF PROGRESS IN ATTAINING SELF-SUSTAINING GROWTH, 1957-62

Source: Table A-1.

Symbols: r = GNP growth rate $k\bar{r}$ = ratio of investment to GNP needed for 5 per cent GNP growth rate I_0/V_0 = investment/GNP ratio in 1962 \bar{i} = annual growth rate of investment α_0 = 1962 ratio of saving to GNP α' = marginal saving/GNP ratio E_0/M_0 = 1962 ratio of exports to imports ϵ = export growth rate μ'/μ_0 = ratio of marginal to average import/GNP coefficients F_0/V_0 = ratio of capital inflow to GNP in 1962 ($I_0/V_0 - \alpha_0$),

* Criteria:

(a) Saving criteria: $\alpha' \geq k\bar{r}$, or $\alpha_0 \geq k\bar{r}$, where $\bar{r} = .05$

(b) Trade criteria:

$$\frac{\mu'}{\mu_0} \leq \frac{(E_0/M_0)(1 + \epsilon)^p - 1}{(1 + \bar{r})^p - 1}, \text{ for some } p \leq 50 \text{ years where } \bar{r} = .05$$

(c) Minimum investment criteria: The initial investment rate of the countries marked by an asterisk is insufficient to maintain a 5 per cent GNP growth rate, even if the capital-output ratio were to fall to 3.0 (i.e. $I_0/V_0 < .15$), and the rate of increase in investment is insufficient to ever achieve a 5 per cent GNP growth rate (i.e., $\bar{i} < .05$).

* Do not meet either set of investment criteria.

not meet either investment criterion for the period 1957-62.

The 12 countries in group A satisfy the criteria for approaching or maintaining self-sufficiency and nine of them have already achieved growth rates of 5 per cent or more. Half of this group is heavily dependent on external capital for its continued growth, while most of the others have favorable exports and little or no net capital inflow.

Of the 19 countries that fail to satisfy one or both criteria for approaching self-sustaining growth, failure on the trade side seems to be at least as important as deficiencies in saving and investment. More detailed studies suggest that a number of these countries—India, Greece, Turkey, Chile, Colombia, Costa Rica, Bolivia, Guatemala, and Honduras—have recently shown symptoms associated with Phase III in our model: import shortages, substantial excess capacity, and in some cases falling saving rates.⁴⁸

One of the most suggestive features of this grouping of countries is the predominant role played by exports. Ten of the 12 countries in group A have export growth rates of 6 per cent or more and hence could eventually reach self-sustaining growth of 5 per cent even if the ratio of imports to GNP remained constant. Conversely, one of the most significant aspects of the unsatisfactory performance of countries in Group D is the stagnation of their exports, which has typically led to increased requirements for external capital and falling saving rates. There is almost no example of a country which has for a long period sustained a growth rate substantially higher than its growth of exports through continuing import substitution. In the past Brazil, Colombia, Turkey, and India have done so for considerable periods, but each has run into severe balance-of-payments difficulties in recent years.

This comparative assessment also tends to dispel the notion that performance as measured here is necessarily associated with the initial income level. In this period, at least, there is little correlation between initial income levels and either marginal saving rates or balance-of-payments performance.

B. Projections of Future Growth

Since less developed countries vary widely in their ability to mobilize their own resources and to utilize external resources, estimates of future assistance requirements based on aggregate models are not very useful. We have therefore made a series of projections for each of 50 countries in order to explore the range of future growth possibilities and corresponding assistance requirements. While the projection for any single country is fairly crude, this approach has the great advantage of taking into

⁴⁸ Aggregate evidence is given in [8]; examples of more detailed analyses of the trade gap are found in [1] [14] [24] [25].

account absorptive capacity, import requirements, and other limitations which can only be judged on a country basis.

Our analysis is designed to explore the possibilities for accelerating growth through a combination of improved country performance and additional external resources. We therefore specify a considerable range of performance possibilities, based on the preceding survey of current performance. The range of values chosen for each parameter is designed to show the extent to which the performance variables affect the country's growth and its aid requirements.

1. *Methodology.* The methodology to be used follows closely that used for Pakistan in Section I. A similar range of variation in performance has been specified for each of the 50 countries in the sample. Principal attention has been given to the 25 countries having the largest effect on assistance requirements.

As a starting point we estimated the six parameters in model 1 from the historical performance in each country, modified in some cases by the experience of similar countries. The average of the resulting target growth rates for all countries (projected to 1975) is 4.4 per cent, approximately the same as the recent past.⁴⁹

To evaluate the possibilities for accelerated growth, we divided the six policy parameters into three groups: the growth limits for investment and GNP (β and τ); internal performance factors (k , α' , and μ'); and export growth (ϵ). Starting from the historical estimates, we specified two sets of more optimistic assumptions for growth limits and internal performance factors and one alternative set of export projections.⁵⁰ These alternative sets of parameters values are shown in Table A-2. The possible combinations of the sets of values for the parameters provide a basis for 18 projections for each of the 50 countries.

In judging the range of possible performance for each country, we took into account its historical performance, its development plan, the observed performance of other countries and some aspects of political performance. We relied heavily on the development programs of the major countries in making the intermediate or "plan" estimates of both growth targets and internal performance. "Plan" targets and performance are defined here as those achievable with moderate improvements in development policies in relation to past experience. The most optimistic (upper-limit) estimates assumed that almost all countries could attain the median observed value of the marginal saving rate (.20) and

⁴⁹ These historically based estimates are shown in Table A-2 of the Annex. They differ from the estimates in Table A-1 for 1957-62 primarily in the elimination of abnormal or biased values that need not persist with reasonable policies—e.g., falling export and saving rates, abnormally high capital coefficients, etc. In large part, these abnormal values represent the effects of disequilibrium conditions on our estimates. The revisions reduce the estimates of aid requirements.

⁵⁰ Details are given in [8].

could limit the marginal import coefficient to the normal value derived from intercountry comparisons.

Our notion of the upper limit implies a probability of perhaps one in four that the given target growth and performance could be attained. For all countries, the average of the plan growth targets through 1975 turns out to be 5.2 per cent and the average of the upper-limit targets is about 6 per cent. The "plan" estimates range from 3–9 per cent with a heavy concentration between 5 per cent and 7 per cent.⁵¹

In order to explore the range of growth possibilities systematically, we have adopted the same degree of optimism for all countries in each trial calculation. Projections on this basis are designed to reveal the range of possibilities that is interesting for policy purposes rather than to forecast the most probable course of development in each country. The projections were made from year to year according to the formulas of the appropriate phase in model 1.⁵² Cumulative results for the 18 combinations of growth targets, country performance, and exports are given in Table 8 and regional projections for 1970 and 1975 in Table 9.

The projections based on model 1 include measures of excess consumption and excess imports, which show the extent to which aid requirements could be reduced through policies designed to equalize the

⁵¹ Whatever the validity of our subjective judgments as to the possibility of improved performance, this procedure has seemed preferable to a more mechanical approach to testing the sensitivity of the results to various types of change. Our principal conclusions are not greatly affected by differences in judgment as to the possibilities for individual countries.

⁵² Machine computations involve a test in each year to determine the appropriate growth phase and set of equations to apply for the next year.

^a See Table A-2 for values of parameters used and Table A-3 for initial values of variables used.

^b Foreign resource flows are measured on a net basis. In any particular year most net flows are capital inflows, but some countries (e.g., Venezuela, Malaya, Burma) may have estimated potential capital outflows under the assumptions made. This alternative net capital estimate shown here excludes these potential capital outflows.

^c The figures shown here exclude potential capital outflows (see Table 8, note b); regional totals are denoted by an asterisk (*) if they include such a case.

^d Excludes Cuba, China, North Korea.

two resource gaps. Since the empirical possibilities for such policies cannot be ascertained without detailed studies of each country, we will apply the over-all factors derived in Section I to estimate the reduction in capital inflow that might be achieved in this way.

2. *The Phases of Growth.* The projection of growth paths under alternative assumptions provides a more general evaluation of the relative importance of the two resource limitations than does our attempted identification of these limits in current situations. Table 7 shows the proportion of the 50 countries in which the saving-investment gap was the limiting factor—and hence the determinant of capital inflow—in each of the 18 trial projections. The most striking result of this tabulation is the predominance of the trade limit; it is more important than the saving limit in 1975 in 15 of the 18 sets of alternatives.

This breakdown shows the quantitative significance of three factors that have been discussed previously in general terms.

(1) At higher growth rates the saving limit tends to become more important, for reasons analyzed in Section I. Under most assumptions as to the other parameters, a rise in the growth rate from the historical average of 4.4 per cent to the upper-limit average of about 6 per cent increases the number of countries in which the saving limit is controlling by 50 per cent or more.

(2) The saving limit is increasingly dominated over time by the trade limit under historical conditions of internal performance. This result points to the need for more import substitution unless export prospects can be drastically improved.

(3) A 40 per cent increase in the assumed rates of growth of exports (from the low to the high assumptions) removes the trade limit in only four to six of the 50 countries under most assumptions. Unrealistically large increases in exports would be required to reduce greatly the importance of the balance of payments limitation by 1975.

C. Development Performance and Assistance Needs

The projections in Table 8 are designed to show the way in which assistance need vary with the export possibilities and internal performance of the developing countries. For this purpose the 900 separate country projections have been aggregated using the same degree of optimism as to exports and internal performance for each country. To summarize the results graphically, the 18 aggregate solutions of Table 8 are plotted in Figure 4, giving three points on each of the six curves. Curve *P2*, for example, shows the increase in cumulative capital inflow from \$100 billion (\$7.7 billion per year) needed to sustain an average growth rate of 4.4 per cent to \$173 billion (\$13 billion per year) to sustain a growth rate of 5.8 per cent, assuming plan performance and high exports.

FIGURE 4. FOREIGN CAPITAL REQUIREMENTS OF 50 DEVELOPING COUNTRIES
ALTERNATIVE DEVELOPMENT PATTERNS, 1962-75
(All values in billions of 1962 U.S. dollars)

Source: Table 8.

The graphical presentation facilitates analysis of the product of external assistance under alternative assumptions. Along curve increase of a billion dollars of GNP in 1975 can be secured for a aid input of \$1.2-\$1.3 billion between 1962 and 1975.⁵³ The tivity of aid is significantly lower with historical performance nificantly higher with upper-limit performance, as shown by the

⁵³ An alternative calculation would show a cumulative addition to GNP over the nearly five dollars per dollar of capital inflow. There is some decline in aid product higher growth rates due to the shifting of countries from Phase III to Phase II.

slopes of the curves.⁵⁴ Variation in export optimism affects the level of total aid but not its marginal productivity.

The effects of individual elements can be isolated in Table 8. Starting from the central estimate of \$131 billion in capital imports for plan growth, high exports, and plan performance, we can identify the following effects of changes in different sets of policy variables:

(1) *A decrease in export growth from 5.2 per cent to 3.8 per cent* causes a reduction of exports of \$39 billion and an increase of total capital inflow of \$21 billion.

(2) *An increase in internal performance to the upper limit* (with a constant growth rate) causes a reduction of capital inflow by \$32 billion.

(3) *A fall in the growth rate to 4.4 per cent* (with no change in internal performance) causes a reduction in external capital requirements of \$31 billion and of consumption by \$98 billion.

The relative importance of these changes varies with the starting point and depends largely on which of the growth limits predominates. At the upper limit growth rates, where the saving constraint is more important, the effect of increasing exports on aid requirements is less.⁵⁵ At plan growth rates, about half of any increase in exports is reflected in a reduced need for external resources in the model 1 solutions, since the external requirements of countries in Phase II are not affected.

Perhaps the most notable feature of this analysis is the sensitivity of aid requirements to variations in internal performance. At historical growth rates, the maximum reduction due to improved performance is about 20 per cent, but at the 6 per cent growth rate, upper-limit performance would reduce external capital needs by 40 per cent. Put in other terms, the capital inflow required to sustain 4.4 per cent growth with historical performance would sustain 5.4 per cent growth if all countries could achieve the upper-limit standards. The main cause of the greater sensitivity at higher growth rates is the greater importance of saving out of increased income as GNP grows. This sensitivity would be even more pronounced if we assumed that saving depends on per capita rather than total income levels.

To compare our results to other estimates, we can state them in terms of the net capital inflow in 1970 and the implied increase in external assistance between 1962 and 1970. Omitting the less likely combinations of assumptions, the indicated range of capital requirements in 1970 is

⁵⁴ The marginal productivity of aid in the three high export cases is .54 for historical performance, .81 for plan performance, and 1.54 for upper-limit performance. Corresponding values derived above from equations (18) and (19) using median observed values of the parameters were .35 for Phase II and .91 for Phase III.

⁵⁵ This effect is more pronounced at low growth rates if we do not exclude countries having capital exports.

from \$10–\$17 billion,⁵⁶ corresponding to the rate of growth of external capital of 3 per cent to 10 per cent from its \$7.4 billion value in 1962.⁵⁷ This range compares to the U.N. estimate for 1970 of \$20 billion and to Balassa's range of \$9–\$12 billion [4]. Our estimates have the advantage of making explicit assumptions as to country performance and of showing how the total depends on them.

The possibility of further reduction in assistance needs through better development policies is indicated in Table 8 by the magnitude of the excess imports for countries in Phase II and unrealized saving for countries in Phase III. With the moderate improvement of performance that is represented by the plan growth targets and plan performance, there would be \$98 billion of unrealized saving and \$20 billion of excess imports. The predominant need is to convert the unrealized saving into additional investment which will substitute for imports or increase exports.

The theoretical limits to the possibilities for reducing aid requirements in this way are shown in Table 9. As explained in Section I.D, the efficiency of the import substitution mechanism in converting surplus saving into a reduction in capital requirements may be on the order of 50–65 per cent under plausible assumptions. More massive import substitution would raise the marginal capital coefficient for the additional production and thus lower the possibilities for efficient reductions in external capital.

To illustrate the extent to which further import substitution or additional exports might reduce assistance requirements by 1975, we have made a set of projections with model 2 on the assumption that not more than 10 per cent of total investment in each country could be devoted to this purpose. The results are shown in Table 10. They suggest that optimum planning for structural change might reduce requirements for external capital in 1975 by a third or more at plan growth rates compared to the more rigid trade assumptions of model 1.

Some of the regional implications of the projections are brought out in Table 9. The regional growth rates corresponding to the average plan target of 5.2 per cent vary from 4.2 per cent for the sample of African countries to 6.0 per cent in the Near East. South Asia shows the most rapid increase in capital inflow relative to its growth in GNP, reflecting its relatively high absorptive capacity and relatively low initial savings

⁵⁶ The principal combinations for 1970 are given in Table 9 and the full range for 1975 in Table 10.

⁵⁷ We have used a factor of 1.25 to convert our sample results to the requirements of all less developed countries. The 1962 figure of \$7.4 billion is based on balance of payments figures in [21], Tables 1 and 11, and is lower than the OECD estimate of \$8.5 billion of capital inflow in the same year. It includes capital flows to Turkey and Greece, and excludes Puerto Rico and \$0.7 billion of capital outflows from major oil exporters. The discrepancies between the U.N. and OECD estimates are discussed in [22, Annex, pp. 6–8].

^a External capital requirements exclude negative flows (capital outflows) from countries estimated to be net potential capital exporters by 1975.

^b Estimated by assuming conversion of "excess imports" (Table 8) to additional import substituting investment in amounts not exceeding 10 per cent of total investment estimated for equivalent model 1 development alternative. The 1975 external capital "saving" under this assumption range from \$3.4 to \$9.5 billions.

rates. Perhaps more significant than the actual estimates is the demonstration that the allocation of external assistance in accordance with comparable standards of performance would be likely to result in substantial shifts in the regional distribution of foreign assistance.

III. International Assistance Policies

Our analysis has shown the conditions under which external assistance may make possible a substantial acceleration in the process of economic development. It has focused on the interrelations among external resource requirements and the development policies of recipient countries. Analysis of these interrelations leads to several principles of general applicability to international assistance policy.

The central questions for assistance policy are the measurement of the effectiveness of external assistance, the policies which recipient countries should follow to make best use of external resources, and the basis for allocating assistance among countries. This concluding section summarizes the main implications of our analysis for each of these questions and adds some qualitative elements which have been omitted from the formal analysis.

A. *The Effectiveness of Assistance*

In the short run the effectiveness of external resources depends on their use to relieve shortages of skills, saving, and imported commodities. The productivity of additional amounts of assistance over short periods can be measured by the increase in output resulting from the fuller use of domestic resources which they make possible.

Over longer periods, the use that is made of the initial increase in output becomes more important. Even if the short-run productivity of aid is high, the economy may continue to be dependent on external assistance indefinitely unless the additional output is allocated so as to increase saving and reduce the trade gap. Over the whole period of the transition to self-sustaining growth, the use that is made of the successive increments in GNP is likely to be more important than the efficiency with which external assistance was utilized in the first instance. This was demonstrated in the discussions of Figure 3 in Section I, which showed the dependence of total aid requirements on the marginal saving rate. To emphasize this point, let us assume that the productivity of investment in the first five years of the upper-limit development sequence outlined above for Pakistan had been one-third lower, requiring a correspondingly larger amount of investment and external aid to achieve the same increase in GNP. The effect would be to increase the total aid required over the 17-year period to achieve self-sufficiency by some 45 per cent. This, however, is less than the effect on aid requirements of a reduction in the marginal saving rate from .24 to .22. The critical elements in the development sequence are getting the initial increase in the rate of growth, channeling the increments in income into increased saving, and allocating investment so as to avoid balance-of-payments bottlenecks. These long-run aspects are likely to be considerably more important than the efficiency with which external capital is used in the short run.⁵⁸

The long-run effectiveness of assistance is also likely to be increased by supporting as high a growth rate as the economy can achieve without a substantial deterioration in the efficiency of use of capital. This conclusion was derived in [8] and is elaborated in [7]. There are also several factors omitted from the formal models that argue for more rapid growth:

- (1) The fact that a smaller portion of the increase in GNP is offset by population growth;
- (2) The gain in political stability and governmental effectiveness that is likely to result;

⁵⁸ This conclusion is demonstrated in the evaluation of the effectiveness of aid to Greece in [1].

(3) The greater likelihood of being able to raise marginal saving rates and export growth when GNP is growing more rapidly;⁵⁹

(4) The greater likelihood of attracting foreign private investment to finance the needs for external capital.

While the last three factors cannot be measured with any accuracy, they appear to have been important in most countries that are successfully completing the transition, such as Israel, Greece, Taiwan, Mexico, Peru, and the Philippines. These examples support the theoretical conclusion that the achievement of a high rate of growth, even if it has to be initially supported by large amounts of external capital, is likely to be the most important element in the long-term effectiveness of assistance. The substantial increases in internal saving ratios that have been achieved in a decade of strong growth—from 7 per cent to 12 per cent in the Philippines, 11 per cent to 16 per cent in Taiwan, 6 per cent to 14 per cent in Greece, and -9 per cent to 12 per cent in Israel—demonstrate the speed with which aid-sustained growth can be transformed into self-sustained growth once rapid development has taken hold.

B. Policies for Recipient Countries

While the receipt of external assistance may greatly reduce the time required for a country to achieve a satisfactory rate of growth, dependence on substantial amounts of external resources creates some special policy problems. One lesson from the preceding analysis is that the focus of policy should vary according to the principal limitations to growth. Just as optimal countercyclical policy implies different responses in different phases of the business cycle, optimal growth policy requires different "self-help" measures in different phases of the transition.

In Phase I, where the growth rate is below a reasonable target rate, the focus of policy should be on increasing output, implying an increase in the quality and quantity of both physical capital and human resource inputs. Our statistical comparisons suggest that a rate of growth of investment of 10–12 per cent is a reasonable target for countries whose initial investment level is substantially below the required level. Phase I can be completed by most countries in a decade if this increase in investment is accompanied by sufficient improvement in skills and organization to make effective use of the additional capital that becomes available. Although it is probably more important in this phase to focus on securing increases in production and income, a start must also be made on raising taxes and saving if international financing is to be justified by performance.

As Phase I is completed, the rate of increase in investment can be

⁵⁹ The advantages of more rapid growth with constant per capita marginal saving rates are demonstrated by Fei and Paauw [9].

allowed to fall toward a feasible target rate of GNP growth, which is unlikely to be more than 6-7 per cent. The focus of development policy should then be increasingly on (a) bringing about the changes in the productive structure needed to prevent further increases in the balance of payments deficit, and (b) channeling an adequate fraction of increased income into saving. Although theoretical discussion has tended to stress the second requirement, the first appears to have been more difficult in practice for many countries. Since substantial import substitution is required just to prevent the ratio of imports to GNP from rising, export growth at least equal to the target growth of GNP is likely to be necessary in order to reduce external aid.

As the focus of development policy changes, the instruments of policy must change accordingly. Somewhat paradoxically, successful performance in Phase I, which would justify a substantial and rising flow of foreign assistance, may make success in Phase III more difficult. If investment and other allocation decisions are based on the exchange rate that is appropriate for a substantial flow of aid, they are not likely to induce sufficient import substitution or increased exports to make possible a future reduction in the capital inflow. Planning should be based on the higher equilibrium exchange rate that would be appropriate to a declining flow of aid in order for the necessary changes in the productive structure to be brought about in time.

It is the need for rapid structural change which sets the lower limit to the time required to complete the transition to self-sustaining growth. Even though the simplified model underlying Figure 3 suggests the possibility of completing this transition in less than 20 years starting from typical Asian or African conditions, it is very unlikely that any such country can meet all the requirements of skill formation, institution building, investment allocation, etc. in less than one generation.

C. Policies for Donor Countries

Donors are concerned with criteria for the allocation of aid among recipients, and the means for controlling its use. Allocation and control policies are complicated by the mixture of objectives that motivate international assistance, the most important of which are (i) the economic and social development of the recipient, (ii) the maintenance of political stability in countries having special ties to the donor, and (iii) export promotion. This mixture of motives has led to a complex system of aid administration in all countries.

The predominant basis for development loans is the individual investment project, for which external financing is provided to procure capital goods from the donor country. Loans not limited to equipment for specific projects are provided to a few selected countries against the

balance-of-payments needs of development programs.⁶⁰ Substantial but declining amounts of grants are also furnished for budgetary support of ex-colonies and other dependent areas.

Our analysis suggests some directions in which improvements can be sought in the present methods of supporting economic development, which is the objective on which all parties agree. We consider first methods of transferring resources to individual countries and then allocation of assistance among countries.

1. *The Transfer of Assistance.* Any system for transferring resources must include: (i) a basis for determining the amount of the transfer, (ii) specification of the form of resources to be furnished, and (iii) a basis for controlling their use. On all these counts the project system has the virtue of simplicity. It also provides for detailed evaluation of the investments that are directly financed from external aid—which may be 10 per cent or so of total investment—and for increasing their productivity through technical review.

While the project system has much to commend it when the main focus is on increasing the country's ability to invest, it becomes increasingly inappropriate as the development process gets under way. As the rate of growth increases, we have shown that the effectiveness of aid depends more on the use that is made of the additional output than on the efficiency with which a limited fraction of investment is carried out. Furthermore, an attempt to finance the amount of external resources needed during the peak period of an optimal growth path—which may imply aid equal to 30–40 per cent of total investment—by the project mechanism alone may greatly lower the efficiency of use of total resources. Limiting the form of assistance to the machinery and equipment needed by substantial investment projects is likely either to lower the rate of growth or to distort the pattern of investment.

In these circumstances, assistance would be more effective if the range of commodities supplied could be broadened to permit the recipient's pattern of investment and production to evolve in accordance with the principle of comparative advantage.⁶¹ While domestic supply can—and indeed must—lag behind demand in some sectors to accommodate the needed resource transfer, the country should also be preparing to balance its international accounts by the end of a specified transitional period.

Since donors fear that uncontrolled imports may be wasted in increased consumption without the restraints imposed by the project

⁶⁰ In the terminology of AID [2], the latter are called program loans. About half of U.S. development lending is on a program basis in contrast to a much smaller proportion for other OECD Development Assistance Committee members or the World Bank.

⁶¹ This observation applies to aid in the form of agricultural commodities as well as to aid in the form of machinery or any other specified goods.

mechanism, an alternative means of control is needed. Part of the solution lies in relating the amount of aid supplied to the recipient's effectiveness in increasing the rate of domestic saving, so that the added aid will necessarily increase saving and investment as income grows. As development planning and statistics on over-all performance improve, this type of "program approach" is becoming increasingly feasible, both from the point of view of determining the amounts of assistance needed and of assessing the results.⁶²

The strongest argument for the program approach arises for countries in Phase III, where the balance of payments is the main factor limiting growth and there is typically excess capacity in a number of productive sectors. In this situation, the highest priority use of imports is for raw materials and spare parts to make more effective use of existing capacity; project priorities should give primary weight to import substitution and increased exports. In this situation donor controls should be primarily concerned with the efficient use of total foreign exchange resources, which can only be assessed adequately in the framework of a development program.

2. *Allocation of Assistance.* If the objectives of the donor countries could be expressed as some function of the growth of each recipient, it would be possible to allocate aid primarily on the basis of expected development performance. The varying political objectives of the donors complicate the problem because each would give somewhat different weights to a unit of increase in income as among recipients. Even with this limitation, however, there may be considerable scope for reallocating a given amount of aid or for selective increases in individual country totals in accordance with criteria of self-help.

The predominant project approach now in use favors countries whose project preparation is relatively efficient. Other qualities that are equally important to successful development—tax collection, private thriftiness, small-scale investment activity, export promotion—are ignored in focusing on this one among many aspects of better resource use.⁶³

Where fairly reliable statistics are available, an alternative procedure would be to establish minimum over-all performance standards for each country and to share the aid burden among interested donors through a consortium or other coordinating mechanism. For example, a country starting in Phase I might have as its principal performance criteria: (i) growth of investment at 10 per cent per year at a minimum standard

⁶² The U.S. government has been using the program approach in India, Pakistan, Turkey, Tunisia, Chile, Colombia, and Brazil. See AID [2] and [3].

⁶³ It is perhaps more than coincidence that most of the striking successes in development through aid—Greece, Israel, Taiwan, etc.—were financed largely on a nonproject basis.

of productivity, and (ii) the maintenance of a marginal saving rate of .20 (or alternatively a specified marginal tax rate). There would be little possibility to waste aid on these terms, since the required increase in savings would finance a large proportion of total investment. Appropriate over-all standards for saving rates and balance-of-payments policies for countries in Phase II and Phase III could also be established without great difficulty. A country maintaining high standards—say a marginal savings rate of .25 and a marginal capital-output ratio of less than 3.3—could safely be allotted whatever amount of aid it requested in the knowledge that the larger the amount of aid utilized, the higher would be its growth rate, and the more rapid its approach to self-sufficiency.

STATISTICAL ANNEX

The three tables in this annex contain the values of the structural parameters, both observed (Table A-1) and projected (Table A-2), as well as base-year (1962) values of the six variables (Table A-3), on which the 50-country projections of model 1 were based. Data sources were the U.N. *National Accounts Yearbooks*, Statistics and Reports Division of the Agency for International Development, and the *Balance of Payments Yearbook* of the IMF. Projections of the structural parameters were based on individual country studies or, where these were not available, informed judgments of country experts. These projections were made in the autumn of 1964 and reflect the best estimates available in the spring and summer of that year.

Revisions of both the historical data and the projections of structural parameters were made a year later, in the autumn of 1965, as a part of AID's continuing study of prospective worldwide foreign capital requirements. Only Table A-1, showing the structural relationships observed over the period 1957-62, has been revised here, however.

Important changes in the base-year data include downward revisions in both investment and savings for India and Argentina, smaller capital inflows for Argentina and Brazil, and a higher investment figure for Brazil. These changes would not, however, greatly influence the projected foreign resource requirements for the fifty-country aggregate. On the other hand, the 1965 projections gave substantially different results in some cases than the earlier ones had because of changes in the projected structural parameters. Most important of these were increased export growth rates⁶⁴, higher upper-limit target growth rates for GNP, and lower upper-limit capital-output ratios for India and Pakistan. The net effect of all changes was to

⁶⁴ Projections based upon the export parameters initially obtained for this sample gave 50-country export growth rates ranging from 5.5 to 6.5 per cent. Since these potential increases were considerably higher than most forecasters believe possible for the less developed world, each country's rate was proportionately reduced so as to give a 1962-70 combined export growth rate of 3.7 per cent as one alternative and a rate of 4.9 per cent as a second alternative. These scaled down parameters are shown in Table A-2. The same optimistic attitude toward export potential produced a subsequently revised set of export parameters, used for the 1965 AID projections, implying a combined 1963-70 export growth of 4.6 per cent under the low alternative and a rate of 6.9 per cent under the high option.

narrow the range of foreign resource requirements found for the various parameter combinations. The 50-country totals for 1975, shown as \$12.1-\$17.4 billion in Table 9, dropped to \$10.9-\$12.7 billion in the 1965 projections. The difference is very largely due to the greater export optimism

THE SOVIET COLLECTIVE FARM AS A PRODUCER COOPERATIVE

By EVSEY D. DOMAR*

Imagine that most of the obstacles facing Soviet kolkhozes (collective farms) today, such as output and delivery quotas, administrative interference, shortage of strategic inputs (materials, spare parts, fertilizer), depressed prices of outputs, etc., suddenly vanish, and the kolkhozes find themselves in a Lange-Lerner type of a competitive world where everything can be bought and sold at a market price, and where peasants are free to run their own affairs *provided the essential structure of the kolkhoz is retained*. How would Soviet agriculture, or for that matter any economic sector so organized, fare in such a wonderland?¹

Freed from existing restrictions and abuses, the kolkhoz would presumably revert to its prototype—a producer cooperative which utilizes the labor of its members, purchases other inputs, sells its outputs, pays a rent and/or taxes, and divides all or a part of its net proceeds among its members. The presumed democratic nature of such a co-op and its freedom from capitalist exploitation has made it highly attractive to socialists and social reformers for ages. But its popularity has not prompted its proponents to analyze it with the same loving curiosity that the “bourgeois” economists have shown toward the capitalist firm. And yet it must have been obvious, at least to some of these proponents, that co-op members are likely to be ordinary human beings bent on maximizing the benefits from their participation in the co-op.² The first and only attempt to construct a model of a co-op that I have seen belongs to

* [The author is professor of economics at Massachusetts Institute of Technology.] I am very grateful to Abram Bergson, Michael R. Dohan, John G. Gurley, Michael D. Intriligator, Nancy Nimitz, David McGarvey, and Egon Neuberger for their generous assistance and helpful comments. Questions raised by Mr. Neuberger made me rewrite the whole paper. David Conklin acted as my research assistant, and Martin Weitzman went over the mathematics. I had intended to include in the paper a brief survey of relevant recent Soviet literature, and James R. Millar of Cornell University kindly lent me three chapters of his dissertation [8]. This project was abandoned because of lack of space; besides, Mr. Millar's survey is more comprehensive and thorough than mine could have been. I am also grateful to the RAND Corporation for its facilities, encouragement and support. Some of the research was supported by the National Science Foundation as well. None of these persons or organizations is of course responsible for my conclusions or for any errors which may still be lurking around.

¹ The question is not as academic as it sounds. Recent changes in Soviet agricultural policies represent another step toward that wonderland, though there is still a long way to go [16] [17] [18] [20] [21] [22] [23] [24].

² I do not discuss here producer co-ops organized for essentially noneconomic reasons, such as by religious orders, Israeli pioneers, etc.

Benjamin Ward in a path-breaking paper published in 1958 [12].³ But like many a pioneering work, it has not attracted much attention.⁴

The present study consists of three parts: in the first, Ward's creation, called here the "Pure Model" of a co-op, is reworked with a generalized production function. The tenor of Ward's findings (based on a single-output, one-or-two-input function) is confirmed, but some of the results are made more definite, and one is reversed. In the second part, the co-op is faced with a supply schedule of labor; this makes the model much more realistic and reverses the paradoxical results of the "Pure Model." Finally, a summary and a few conclusions are presented in the third part.

LIST OF SYMBOLS

(in order of appearance)

R —a fixed rent paid by the co-op ($R > 0$)

v — $(-\pi/x_n)$ —dividend rate or dividend per labor unit ($v > 0$)

x_n —labor input ($x_n < 0$)

n —number of outputs and inputs

π —profit of the co-op gross of dividend payments ($\pi > 0$)

p_i —price of x_i ($i = 1, \dots, n-1$)

x_i —an output when $x_i > 0$, an input when $x_i < 0$ ($i = 1, \dots, n-1$)

p_n —wage rate paid by the "capitalist twin"; originally $p_n = v$

λ —Lagrange's multiplier

$E_{x_i, p_j} = (\partial x_i / \partial p_j) \cdot (p_j / x_i)$ —elasticity of demand for, or supply of, x_i in response to change in p_j ($i, j = 1, \dots, n$)

$u_i = p_i x_i$ —value of an output when $x_i > 0$, or of an input when $x_i < 0$.

A few other symbols are defined when introduced.

An asterisk indicates that the expression pertains to the "capitalist twin."

³ There have of course been a number of analyses of firms which do not maximize total profit in the usual way. See for example Scitovsky [10]; F. and V. Lutz [7]; Baumol [5]; Averch and Johnson [4]; and Westfield [13]. A very interesting book on cooperatives was published by Tugan-Baranovsky [11a] in 1921. His conclusions were very similar to mine given in Sec. III of this paper. I owe this reference to Steven Rosefielde of Harvard.

⁴ In my sample of some forty or fifty reputable economists about a third of whom work in the Soviet and related fields, Ward's article had been read by three or four persons at most. Perhaps the paper's title gave the wrong impression that it pertained to Yugoslavia only. Or—who knows—this might have been the normal fate of an excellent paper.

I. The "Pure Model" of a Co-op

Assumptions:

1. All nonlabor inputs are bought and all outputs are sold by the co-op at given (parametric) prices.
2. The production function of the co-op, if possessed by a profit-maximizing firm, would have all necessary and sufficient properties for a stable equilibrium under perfect competition [2] [3].
3. The co-op pays a fixed rent $R > 0$ per year.⁵
4. Instead of paying wages, the co-op divides all (or a constant fraction) of its income net of all other costs and rent equally among its members or among homogeneous labor units in the form of a dividend.⁶
5. The objective of the co-op is the maximization of the dividend per unit of labor or of the dividend rate $v > 0$. There is complete certainty.⁷

⁵ Soviet kolkhozes do not pay rent as such, but the system of compulsory deliveries and differentiated zonal prices is directed against the richer farms and regions and allows the government to extract some rent. Until 1966, the farms paid a 12.5 per cent tax imposed on income net of nonlabor cost (excluding 80 per cent of income from animal products), but gross of dividend payments. The rate could be modified by regional authorities in favor of poorer and against richer farms [11].

Beginning with 1966, the tax rate is set at 12 per cent, and the taxable income seems to exclude two items: (1) profit equal to 15 per cent of nonlabor costs, and (2) dividend payments not exceeding a certain average per member, to be set by the government [17]. If the post-tax dividend rate is indicated by v_t , it follows that

$$v_t = v(1 - t) + \frac{Cet}{L} + wt,$$

where t is the tax rate (12 per cent), e is the 15 per cent exclusion, w is the exemption per member, C is the nonlabor costs

$$\left(C = - \sum_k^{n-1} p_k x_k, \text{ and } k \text{ is the first input} \right),$$

and $L = -x_n$ (to avoid negative numbers). Now, t , e , and w are constants, but C/L is not. Hence the imposition of the tax in its new form will affect economic decisions in the kolkhoz. I am not sure, however, that my interpretation of this tax reform is correct (the official statement being rather confusing). For this reason and to save space, I will disregard the complexities of the tax law both before and after 1966, and mean by the word "tax" a simple proportional levy on profits before dividend payments. But a further investigation of the effects of this new tax may be worthwhile.

⁶ Actually it is the Soviet practice to transform most of the labor of kolkhoz members into a homogeneous sum by a system of weights depending on the required skill and the nature of work. The weights vary from one kolkhoz to another, but the range seems to be around $2\frac{1}{2}:\frac{1}{2}$. If the relative weights correspond to the ratios of the values of the marginal products of the several kinds of labor this is a reasonable procedure. It would not matter if the co-op first paid uniform wages per labor unit (as Ward assumed) and then used the balance of income for dividends.

It should be also noted that a substantial fraction of the income of the kolkhoz is retained by it (the so-called "Indivisible Fund") for reinvestment and improvements, and that this fraction varies from one farm to another and from one year to the next, depending on economic conditions and on administrative decisions.

⁷ No dynamic elements are considered either. Even though some comments about investment decisions will be made, the model essentially refers to the short run.

6. The co-op is *actually able* to employ the optimum number of labor units maximizing the dividend rate. This assumption (used by Ward) distinguishes this model from those presented in Part II.

7. Finally, there exists a profit-maximizing firm, the "capitalist twin," with the same production function and prices as the co-op, and with a wage rate initially equal to the co-op's dividend rate.

We are concerned in this model with a rent rather than with a tax because a glance at expression (1) below will show that neither an income tax (imposed on net income before dividends), nor a poll tax (per unit of labor) would affect the co-op's decisions in the context of this model: the optimum allocation of resources yielding the maximum dividend before the tax remains unchanged by the tax.⁸

The rent is assumed to be positive because an $R < 0$ (a subsidy) would induce the co-op to maximize the dividend rate v by reducing labor input to zero. Even an $R = 0$ can produce this effect if v declines from the very beginning and has no maximum point. We shall assume that R is large enough to give us a meaningful problem but not to eliminate the co-op's net income or to convert it into a loss.

Note that in the generalized production function given in (2), it is customary to express outputs in positive units, and inputs, including labor (x_n), in negative. Hence many derivations in the Mathematical Appendix have seemingly perverse signs, and a minus sign is attached to expression (1).

Our basic problem consists of maximizing the dividend rate

$$(1) \quad v = - \frac{\pi}{x_n} = - \frac{\sum_1^{n-1} p_i x_i - R}{x_n},$$

subject to the production function

$$(2) \quad f(x_1, \dots, x_n) = 0.$$

The solution of equations (1) and (2), while not difficult, is somewhat involved, and can be safely relegated to the Appendix. It is shown there that the equilibrium position of the co-op is identical in every respect to that of its capitalist twin defined in assumption 7. On reflection, this is to be expected: for any given labor input the co-op simply maximizes total profit like the twin, and hence chooses the same outputs and nonlabor inputs. When it comes to labor, the attitudes of the two organizations differ: the twin hires labor until the value of the marginal product equals the wage; the co-op uses labor to the point where the value of the margi-

⁸ In models presented in Part II an income tax does affect economic decisions. A gross receipt tax would have the same effects as a proportional reduction in the price of every output. See note 5.

FIGURE 1

nal product equals the dividend paid (a unit of labor contributing less than the going dividend rate will not be used).⁹ But since the two schedules of the value of the marginal product of labor are identical and the wage paid by the twin initially equals the dividend paid by the co-op (by assumption 7), the labor inputs used by both organizations are identical as well.

The *reactions* of the two enterprises to changes in rent or in prices, however, are altogether different. An increase in R has no (short-run) effects on the twin because it changes neither the value of the marginal product of labor nor the wage rate. But it reduces the dividend rate paid by the co-op and therefore moves the point of intersection between the dividend rate ABC (on Figure 1) and the value of the marginal product of labor EBF further to the right, from B to B' because of the assumed negative slope of EBF . So, as Ward has shown, more labor will be used (OJ' instead of OJ) and (in the absence of Hicks's "regression" [6]) output will increase as well.¹⁰ But before the reader concludes that the best way to increase peasant participation in Soviet kolkhozes is by imposing (or increasing) rents, he should take a look at Part II.

The effect of a price change on the co-op is more complex because both the dividend rate and the value of the marginal product of labor are

⁹ The schedules of the dividend rate and of the value of the marginal product of labor, as used here, are based on the assumption that equilibrium conditions are satisfied for all outputs and all nonlabor inputs all along the schedules. See, however, note 18.

¹⁰ See the Appendix, Sec. 3.

affected.¹¹ If there is only one output (x_1) and labor is the only input, the outcome is certain: a doubling of p_1 will double the value of the marginal product of labor, while the dividend rate, as shown by expression (1) rewritten for this occasion as

$$(3) \quad v = - \frac{p_1 x_1 - R}{x_n},^{12}$$

will *more* than double. The intersection point of the curves EBF and ABC will now move to the left, from B to B' on Figure 2, and both the labor input and hence the output will contract, as proved by Ward.

With one output and several inputs the situation becomes clouded, but a plausible assumption (that the isoquants of the production function are radially parallel to each other) saves the day and preserves the restrictive conclusion just reached.¹³ The solution of the general case of several outputs and inputs is given in the Appendix;¹⁴ the results are summarized in Table 1.

On the whole, the co-op's reactions to an increase in p_1 are rather peculiar. When x_1 is an output, there is a general tendency to restrict operations; when x_1 is an input—to expand them. Even when the co-op moves in the same direction as a capitalist firm, its response is usually more sluggish. For market stability, the picture is not particularly reassuring.

True enough, if x_1 is one of several outputs, a rise in its price is likely to *increase* its production; its own market can therefore be stable, contrary to Ward's expectations based on the one-output production function. But the input of labor is very likely to decrease and hence lead to a contraction of other outputs. Since many agricultural products are reasonably good substitutes for each other, the conditions which have led to a rise in the price of, say, wheat may very well raise the prices of rye and corn as well. The simultaneous rise in several prices, being similar to the rise in the price of some *important* single user of labor (see the first line of Table 1), can cause a general restriction of output. Although a negatively sloping supply curve is not a sufficient condition for market instability, it is too close to it for comfort.

¹¹ The values of the marginal products of other inputs will also be affected.

¹² The relative increase in v is greater than in p_1 because R is subtracted from $p_1 x_1$ in the numerator. However, x_1 and x_n also change. It is shown in the last section of the Appendix that

$$\frac{dv}{dp_1} \cdot \frac{p_1}{v} = \frac{p_1 x_1}{p_1 x_1 - R} > 1$$

if the production function consists of x_1 and x_n only. See also Sec. 3(a) of the Appendix.

¹³ Appendix, Sec. 3(b).

¹⁴ Appendix, Secs. 3(c) and 3(d).

Of course the undesirable negative effect of the rise in p_1 can be counteracted by an appropriate increase in rent. But such manipulations of rent in response to changing prices would require more knowledge and skill than are likely to be possessed by the Soviet or, for that matter, by most other governments. And besides, the whole idea of rent implies a sum fixed in advance for a reasonably long period of time. It would not help to replace it with a tax on net income because (as mentioned above) such a tax does not affect co-op's decisions. Some other tax might, but it is hardly worth investigating in the light of Part II to come.

The model augurs little good for the allocation of resources among the co-ops. As Ward has observed, the labor market will be rigid. Indeed, if a rich and a poor co-op should each be in its respective equilibrium, no movement of labor from the poor co-op to the rich is possible (except through a merger) because any movement would reduce the dividend rates in both co-ops. Since the dividend rate in equilibrium equals the net value of the marginal product of labor, there is a definite misallocation of labor, and of course of other resources as well, among the co-ops. The hiring of the members of the poor co-op by the rich is the obvious solution, but it is not permitted in the present model.

The best measure both on equity and resource allocation grounds to be taken here is an increase in the rent paid by the rich co-op (or a relief for the poor one, if it pays any). Equity alone could be satisfied by a system of differential prices both for outputs and for inputs discriminat-

FIGURE 2

TABLE 1—A SUMMARY OF THE EFFECTS OF AN INCREASE IN p_1 ON THE
MAGNITUDES OF OUTPUTS AND INPUTS
(in absolute terms)

Effect on	Usual Capitalist Reaction	Probable Co-op Reaction
x_1	If x_1 is an Output: Positive	Positive, unless x_1 is a very important user of labor (or the only output)
$ x_n $	Positive	Negative (except in a special case in the Appendix)
x_2 as all other outputs	Positive, if x_2 is complementary to x_1 Negative, if x_2 is competitive with x_1	Negative if input proportions remain unchanged; otherwise, indeterminate
$ x_2 $ as an input	Positive	Negative
	If x_1 is an Input:	Negative with high complementarity between x_2 and x_n Indeterminate with partial complementarity Positive if x_2 and x_n are substitutes
$ x_1 $	Negative	Negative, except for constant proportions between x_1 and x_n when the effect is zero
$ x_n $	Negative if x_1 and x_n are complementary Positive if they are substitutes	Positive, except for a zero effect if x_1 and x_n are used in constant proportions
x_2 as an output (or all output)	Negative	Indeterminate
$ x_2 $ as an input	Negative if x_1 and x_2 are complementary Positive if they are substitutes	Indeterminate

ing against the rich co-op,¹⁶ but the equalization of the dividend rate so achieved would obviously not equate the social value of the marginal product of labor (and of other inputs) in the two co-ops.

All these equalizing measures can backfire if the wealth of the rich co-op is due not to its better natural conditions and location, but to greater effort and interest of its members not accounted for in the conventional measures of labor input. But these considerations are outside of the scope of this model and even of this paper.

In making investment decisions, each co-op will behave like its own capitalist twin paying a wage rate equal to the co-op's dividend rate. For the rich co-op labor is expensive, for the poor—it is cheap. Hence the former will prefer ready-made labor-saving machinery, while the latter will look for labor-using projects and be inclined, for instance, to use its own labor in construction. To the extent that the poor co-op is poor

¹⁶ A standard remedy in Soviet literature and practice.

because of shortage of capital, it will be more inclined to invest than the rich. Whether it will have the means to do so is less likely.

II. *The Model with a Supply Schedule of Labor*

The "Pure Model," for all its interesting and amusing (I hope) paradoxes, has one slight defect: it is unreal. It assumes that labor input can be varied with changing prices and rent in order to maximize the dividend rate (assumption 6), a highly unlikely situation once the co-op has been organized. Surely the co-op, by its very nature, cannot admit and expel members at will. Hours of labor contributed by each member can of course be varied, but it is rather improbable that the members' welfare functions should call for a maximum dividend either per hour or per year irrespective of the number of hours worked.

Two possibilities will be considered here. First, the number of members is given (at least in the short run), and so is the number of hours contributed (according to some custom) by them. Then labor input is fixed, and the co-op simply maximizes total profit. Second, the co-op members may have other opportunities for employment and for leisure. In Soviet kolkhozes, they may cultivate their own plots, work in town, on a neighboring state farm, or even "lie on the stove" and do nothing according to the age-old Russian custom. In other words, the co-op is faced with a supply schedule of labor, which will be assumed here to have the usual positive slope. The equilibrium position of the co-op is found in two steps: first the co-op maximizes total profit for every given labor input, and obtains the familiar dividend rate curve *ABC* on Figure 3. The latter now serves as the demand schedule for labor as well, and its intersection with the labor-supply curve determines the labor input contributed by members *acting as such*. It need not correspond to the highest point *B* on the *ABC* curve, where it is intersected by the marginal curve *EBF*.

The appearance of this innocent-looking supply curve of labor produces a drastic difference in the reactions of the co-op to changes in prices and in rent as compared with the "Pure Model." Also, an income tax imposed on the co-op's income gross of dividend payments, ineffective previously, becomes relevant here.¹⁶ Depending on the position of the labor-supply curve in relation to *ABC*, three variations of the present model will be discussed.

Case 1. Moderate Labor Shortage

The supply curve of labor *HKM* in Figure 3 intersects the dividend-rate curve *ABC* at *K*, to the left of the maximum point *B*. If, to preserve

¹⁶ For practical reasons, we need not bother with a poll tax. In any case, its effects are similar (but not identical) to those of the income tax. Income or poll taxes imposed on the members (rather than on the co-op) are not considered here. See note 5.

FIGURE 3

the purity of the co-op, no discrimination among its members is permitted, the co-op has to reconcile itself to the situation and simply stay at point K .¹⁷ But its paradoxical behavior disappears. Any improvement in the dividend rate, be it from lower rent or taxes, or from better prices, lifts the ABC curve, increases the employment of labor, and presumably raises output. In the light of this model, which is much closer to Soviet reality than the "Pure" one, price reforms promulgated by Khrushchev and his successors are justified.

It is not clear what labor cost will be used in making economic decisions. The correct cost should be SJ —the net value of the marginal productivity of labor—but since no one is actually paid this rate, the management may not know what it is.

If it is possible to discriminate among members and to hire those with particularly attractive outside opportunities (or the laziest ones) between K and M , new possibilities open up. In treating its hired members, the co-op will behave *more or less* like a capitalist employer, depending on the standing of these members in the co-op and other circumstances. Three subcases will be considered:

(a) If the hired members have different skills (or if the co-op manage-

¹⁷ Provided it gets to point K in the first place. Point K is stable in both directions, but Q is not. An upward movement from Q will bring the co-op to K , but unfortunately even a slight downward movement from Q can destroy the co-op altogether.

ment is very adroit), the co-op may act as a discriminating monopsonist and pay each of them the wage indicated by the supply curve. The area KJM represents the profit so obtained; presumably it will be added to the dividend paid to the regular members.

(b) The hired members may persuade or force the co-op to hire all of them at the highest wage NM . A smaller profit equal to the area DJM is now made.

(c) As a compromise between these two extremes, the co-op may operate like an ordinary monopsonist, draw the dotted curve KM' , representing the marginal labor cost, to its intersection with the value of the marginal product curve EBF , employ altogether ON' units of labor, pay a wage of $N'T$, and make a profit from hiring of $UJM'T$.¹⁸

In all these cases, the total employment of labor exceeds OS , output expands, and dividend rate rises over the original level of SK .¹⁹ Everyone is better off provided the ordinary members are not consumed with envy. They need not be if the hired members do possess special skills. But if they are common members who refuse to work for the co-op more than the minimum required to retain their membership, the social situation can be rather difficult.²⁰

The reactions of the co-op to changes in rent, income tax and prices now take still another turn and become more similar to those of a capitalist firm. An increase in rent lowers the average ABC curve but leaves the marginal EBF schedule intact. Hence, in cases (a) and (b) no reduction in labor input takes place, except that some members who were previously satisfied with dividends will now demand a wage. But output remains undisturbed. In case (c), however, the fall in the ABC curve has a special effect: now that hiring begins earlier (that is, to the left of point K) the curve KM' moves leftward and intersects EBF to the left of the old point M' . Hence, total employment of labor falls and so does output.

An increase in the income tax rate lowers both the average and the

¹⁸ There is some incongruity among the several curves in Figure 3. Schedules ABC and EBF are drawn on the assumption that the co-op is in equilibrium position in respect to all outputs and all nonlabor inputs for every given labor input, or that with every change in the labor input everything else is adjusted accordingly. The supply curve of labor HKM and the marginal cost of labor curve KM' indicate labor cost only, without allowing for these adjustments. I can take refuge in the approximate nature of Figure 3 used here for illustration only. A similar qualification applies to Figure 4 as well.

¹⁹ It will be above SK but somewhat below the corresponding point on the ABC curve because the latter implies that no members are paid a wage in excess of the dividend.

²⁰ Strictly speaking, we assume either that the labor force is homogeneous, or that more skilled labor is transformed into ordinary labor according to some fixed weights, as it is done in Soviet kolkhozes (see note 6). So a refusal of a carpenter to work for the kolkhoz means his unwillingness to accept a multiple of the dividend rate paid to common workers.

In the text, all members working for the co-op receive *either* the dividend *or* a wage. In reality, some combinations of the two are sometimes encountered (see note 21). But this paper is already too long to analyze such a situation.

marginal curves (because it falls on profit *gross* of dividends) and thus reduces the employment of labor, while better prices raise both curves and have a positive effect on labor and on output.

Without the income tax, the wage rate paid to the marginal hired worker (or to all of them) in cases (a) and (b) equals the net value of the marginal product of labor. In case (c) there is the usual disparity created by monopsony. But the presence of the income tax creates a special gap between the social and private (as seen by the co-op) values of labor's marginal product in all three cases, and distorts allocation of resources.

So far only the hiring of its own members by the co-op has been considered. If the co-op can hire outsiders as well, as for instance a rich co-op hiring workers from a poor one, the allocation of labor may be further improved. The hiring co-op will simply behave like a profit-maximizing firm. We'll return to the hiring-out co-op in Case 3.²¹

Case 2. Severe Labor Shortage

When the supply curve of labor *HM* lies completely to the left of the *ABC* dividend curve, the co-op as such cannot function at all. And yet it *may* be possible to hire every member at the wage demanded by him and still pay a rent! The members may be divided into groups (by skill, for instance) and each group paid a wage demanded by its marginal member. Freedom in hiring certainly increases the flexibility of the organization. Perhaps this is one of the reasons why Soviet state farms who hire all their labor are doing better than the kolkhozes, and why some weak kolkhozes have been transformed into state farms²² [19, p. 19].

Case 3. An Excess Supply of Labor

The supply curve of labor *HKM* intersects the *ABC* curve at *M* to the right of the optimum point *B* in Figure 4. The co-op may be either very

²¹ In the actual operation of Soviet kolkhozes, some discrimination and hiring are permitted. The more skilled members are paid dividends at a higher rate (see note 6). In Abramov's delightful story about a kolkhoz [1] carpenters are paid one ruble a day in addition to the dividend rate. In a *Krokodil* story, two neighboring kolkhozes hire *each other's* carpenters (presumably the carpenters have refused to work for dividends on either farm and demanded market wages). Finally, kolkhozes hire agricultural specialists and other experts and skilled workers. It seems that the richer farms even hire ordinary workers in busy times.

The Soviet government has been recommending to the kolkhozes to pay their members a wage in money equal to some 80 per cent of the expected dividend (for the given type of work). But this was an advance payment of a dividend rather than a true wage. It seems that some of the kolkhozes who have tried to follow this recommendation became short of funds [14]. New measures for alleviating the seasonal shortage of funds in the kolkhozes were announced on January 5, 1966 [23].

²² It seems that the definite wage paid by the state farms has a better incentive effect than the promise of an uncertain dividend. An official promise to investigate the possibility of "guaranteed compensation of labor in all kolkhozes" was recently made [21]. But there are many other reasons for the relative success of state farms, such as the payment of higher wages, and most important—access to the government budget. For that matter, not all state farms have been successful.

FIGURE 4

rich or located far from other employment opportunities. The situation is analytically similar to Case 1. If it is impossible to get rid of some members or to reduce labor input by rationing, the co-op will simply stay at *M*. Any improvement in conditions, such as lower rent and taxes, or better prices, will raise the *ABC* curve and increase the quantity of labor used, as in Case 1. But if each member between *K* and *M* can indeed take an outside job and earn a wage at least equal to the corresponding point of the supply curve, it will be better for all concerned to *hire out* the members in *KM*, and in fairness to them, collect their earnings and pay them the regular dividend. The members who are to the right of point *M* will prefer to remain on their own. In the absence of an income tax, the net value of the marginal product of labor will equal its supply price at *K*, which is good, but since the dividend rate paid to the members will be approximately equal to *SJ* rather than *SK*, there is a danger of overvaluation of labor cost by the management.²³ The presence of an income tax creates the same distortions as in Case 1. When the hiring out of labor is permitted, changes in rent, income tax rates, and in prices in Case 3 will have the same effects on the total employment of labor by the co-op as in Cases 1(a) and 1(b).

The (positive or negative) hiring of members improves the allocation of resources within each co-op, but so long as it is confined to its own

²³ It will be somewhat higher than *SJ* because the *ABC* curve disregards the higher wages earned outside. See note 19.

Perhaps a Soviet kolkhoz can act as a monopolist in hiring out labor. An analysis of this case is similar to that given in Cases 1(b) and 1(c) above.

It should be noted that Figure 4 suffers from the same incongruity as Figure 3. See note 18.

members (as assumed here) the distribution of labor among the co-ops remains unchanged.²⁴ In contrast to the "Pure Model" where the inequality of dividend rates among the co-ops indicated misallocation of labor (and of other resources) and where the transfer of labor from the poor to the rich units was clearly in the social interest, the present situation is ambiguous because the value of the marginal product of labor in each co-op no longer equals (except accidentally) the dividend rate: in Figure 3 it is above the dividend rate, in Figure 4—below it. In the improbable (at least among Soviet kolkhozes) case when Figure 3 depicts a rich unit, and Figure 4—a poor one, the transfer of labor from the poor to the rich co-op will be welcomed by all parties. But in the more realistic case when the poor co-op is to the left of the point *B* (as in Figure 3) and the rich—to its right (as in Figure 4) both co-ops will object to this transfer because the poor co-op seeks more labor (so as to reach point *B*), and the rich—less, while social desirability remains obscured by the differences (in opposite directions) between the value of the marginal product of labor and the dividend rate in each co-op.

III. Concluding Remarks

The results of all our models are summarized in Table 2. I now turn to

TABLE 2—THE EFFECTS OF CHANGES IN RENT, TAX RATES, AND PRICES ON THE EMPLOYMENT OF LABOR BY THE CO-OP

Nature of Change	"The Pure Model"	The Model with a Supply Curve of Labor	
		Without Hiring	With Hiring
Increase in rent	Positive	Negative	Neutral, except in Case 1(c)
Increase in income tax rate	Neutral	Negative	Negative
Improvement in prices	Negative	Positive	Positive

those aspects of Soviet agricultural policy to which this paper may be relevant. I think they can be fairly listed as follows:

1. To increase labor participation in the kolkhozes.
2. To improve resource allocation on the farms.
3. To improve allocation of labor among the farms.
4. To bring about greater equality of income per member (or per labor unit) among the farms.
5. To siphon off the excess purchasing power which will be acquired by some peasants if agricultural prices are moved closer to their marginal costs.

²⁴ Except when the hired-out members of one co-op are hired by another.

All these (and other) aspects have been discussed in Soviet literature in recent years, with point (4)—the high degree of inequality among peasant incomes—receiving particular attention. I have not found a comprehensive distribution of peasant incomes, but it is fair to conclude from various sources that ratios of four to one, of six to one, and even higher, between rich and poor farms are not uncommon.²⁵ This inequality is attacked on equity grounds—unequal pay for equal work, the suggested remedy consisting of price manipulations in favor of the poor and against the rich farms. That both the existing inequality and the remedy for it are linked with allocation of resources is hardly ever mentioned. Perhaps the discussion of these finer points in Soviet literature is premature, plagued as their agriculture still is with crude central planning, administrative interference and other problems.

In making the list of my recommendations based on Table 2, however, I shall retain our initial, though still unrealistic under Soviet conditions, assumptions that the peasants will be free to run the kolkhozes as they see fit (short of disbanding the kolkhoz system altogether)—there have been definite moves in that direction lately—and that relative price ratios will reflect real scarcities. Now a difficult (for an economic theorist) choice must be made between being original, if unrealistic, and being conventional and practical. For what could be more original and striking than recommendations derived from the "Pure Model," namely

²⁵ According to V. N. Starovsky, Director of the USSR Central Statistical Administration, "... in 1961 payments per man-day on about 30 per cent of the USSR's collective farms came to only one-fourth to one-fifth as much as on the 20 per cent of the farms where the pay was the highest" [15]. It is not clear whether Starovsky referred to total or to money incomes only.

In the last few years many changes in Soviet agriculture have taken place, but it is hard to judge whether income inequality among the peasants has gone up or down. The following compilation of the official average kolkhoz money income per household among 66 provinces (*oblasti*) of the Russian Republic in 1960 and 1963 indicates little change [25]:

	1960	1963
Ratio between the fourth and first quartiles of the distribution of the provinces	2.0	1.8
Ratio between the means of the highest and lowest 25 per cent of the provinces	3.1	3.2
Ratio between the highest and the lowest single provinces	8.4	8.6

Among the several republics comprising the Soviet Union, the richest one (in the above terms)—Turkmenia—had almost four times as large an income in 1963 as the poorest one—Georgia [26]. A number of scattered sources indicates that ratios of 2 to 1, 3 to 1, and even higher *within* a republic or a province are quite usual. If so, income disparities between the richer and poorer farms become large indeed, and considerably larger than the ratios stated in the text above. On the other hand, a comparison of money income alone can exaggerate the advantage enjoyed by a cotton-producing area like Turkmenia, or by the seemingly rich Far-Eastern provinces where the price level is likely to be higher than in the more central parts of the country. But it is important to note that these inequalities persist in spite of price differentials against the richer regions.

that rent should be increased (or imposed) and terms of trade turned against the peasants in order to make them work longer and harder for the kolkhoz? This would indeed vindicate Stalin's agricultural policies, even though he had arrived at them without building any models.

Dismissing the "Pure Model," we come to the following list of recommendations:

1. To allow the prices of material inputs and of agricultural outputs to move to their equilibrium levels as determined by demand-supply conditions, even at the expense of a sharp rise in peasant gross incomes.
2. To abolish the income tax paid by the kolkhozes.
3. To impose a rent on each farm related to its location, soil fertility, and other natural conditions.²⁶

If this list is so conventional as to create an anticlimax, I apologize. Now and then conventional economic theory does give the right answers, even when applied to a Soviet kolkhoz. And—I almost forgot to make explicit a rather essential recommendation—that the kolkhoz be permitted to engage in as much positive or negative hiring of labor as it can and wants. If this freedom brings it suspiciously close to a profit-maximizing capitalist firm, the similarity could be declared to be purely coincidental.

* * *

Two *caveats* are in order: (1) These conclusions have been derived from a model which proved to be highly sensitive to seemingly innocent changes in assumptions. If I think that my final creation is fairly realistic, so must Ward have thought about his.

(2) Judged by strictly economic criteria, the co-op has not come out well. But even on these grounds, it is quite possible that a co-op may be more efficient than a capitalist or a state-owned firm in societies where membership in the co-op, as contrasted with hiring out for a job, has a strong positive effect on workers' incentives (though hardly the case in Soviet kolkhozes). And so may the co-op's capitalist cousin—a firm with a profit-sharing scheme.

MATHEMATICAL APPENDIX TO THE "PURE" MODEL

1. *Equilibrium Conditions for the Co-op*

Maximize (1a) subject to (2a)

²⁶ I do not mean to imply that these three measures are all that is required to create a healthy agriculture in the Soviet Union. Others, such as increased investment, may be as, or even more, important, but they are not relevant to this paper. Recent agricultural reforms [16] [17] [18] [21] [22] [23] [24] have raised prices on agricultural products, reduced prices on machinery and vehicles, cut taxes, promised more investment financed by the state, short- and long-term credit, and greater freedom to peasants in decision-making (see note 5). But there was no mention of the imposition of rent as such. Since the Soviet constitution assures the kolkhozes of the free use of their land, the imposition of a formal rent would require a major change which would encounter ideological difficulties.

$$(1a) \quad v = -\frac{\pi}{x_n} = -\frac{\sum_1^{n-1} p_i x_i - R}{x_n},$$

$$(2a) \quad f(x_1, \dots, x_n) = 0,$$

and form with a Lagrange's multiplier

$$(3a) \quad z = -\frac{\pi - \lambda f(x_1, \dots, x_n)}{x_n}.$$

Equating $\partial z / \partial x_i = 0$ ($i = 1, \dots, n$) we obtain

$$(4a) \quad \lambda f_i = p_i \quad (i = 1, \dots, n-1),$$

$$(5a) \quad \lambda f_n x_n = -\pi.$$

To derive second-order conditions, take

$$(6a) \quad dz = -\frac{x_n d\pi - \pi dx_n}{x_n^2},$$

$$(7a) \quad d^2z = -\frac{-\pi x_n d^2x_n - 2x_n d\pi dx_n + 2\pi dx_n^2}{x_n^3},$$

on the assumption that x_n is the only dependent variable, so that

$$d^2\pi = \sum_1^{n-1} p_i d^2x_i = 0.$$

From (2a) and (7a),

$$(8a) \quad d^2z = -\frac{\pi x_n \sum_1^n \sum_1^n f_{ij} dx_i dx_j - 2f_n x_n d\pi dx_n + 2f_n \pi dx_n^2}{f_n x_n^3}.$$

From (1a) and (4a)

$$(9a) \quad d\pi = \lambda \sum_1^{n-1} f_i dx_i.$$

Substituting (5a) and (9a) into (8a), we obtain

$$10a) \quad d^2z = \frac{\lambda}{x_n^2} \left(x_n \sum_1^n \sum_1^n f_{ij} dx_i dx_j + 2dx_n \sum_1^{n-1} f_i dx_i + 2f_n dx_n^2 \right);$$

$$11a) \quad d^2z = \frac{\lambda}{x_n} \left(\sum_1^n \sum_1^n f_{ij} dx_i dx_j + 2 \frac{dx_n}{x_n} \sum_1^n f_i dx_i \right),$$

which can be expressed as

$$\begin{aligned}
 d^2z = & \frac{\lambda}{x_n} \left[f_{11}dx_1^2 + f_{12}dx_1dx_2 + \cdots \left(f_{1n} + \frac{f_1}{x_n} \right) dx_1dx_n \right. \\
 & + f_{12}dx_1dx_2 + f_{22}dx_2^2 + \cdots \left(f_{2n} + \frac{f_2}{x_n} \right) dx_2dx_n \\
 & + \cdots \cdots \cdots \\
 & + \left(f_{1n} + \frac{f_1}{x_n} \right) dx_1dx_n + \left(f_{2n} + \frac{f_2}{x_n} \right) dx_2dx_n \\
 & \left. + \cdots \left(f_{nn} + \frac{2f_n}{x_n} \right) dx_n^2 \right],
 \end{aligned}
 \tag{12a}$$

subject to

$$\sum_1^n f_i dx_i = 0.
 \tag{13a}$$

Since $\lambda/x_n < 0$ (because $x_n < 0$), second order conditions for a maximum of d^2z require that the determinant

$$\begin{aligned}
 (14a) \quad D = & \begin{vmatrix} 0 & f_1 & f_2 & \cdots & f_n \\ f_1 & f_{11} & f_{12} & \cdots & \left(f_{1n} + \frac{f_1}{x_n} \right) \\ f_2 & f_{12} & f_{22} & \cdots & \left(f_{2n} + \frac{f_2}{x_n} \right) \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ f_n & \left(f_{1n} + \frac{f_1}{x_n} \right) & \left(f_{2n} + \frac{f_2}{x_n} \right) & \cdots & \left(f_{nn} + \frac{2f_n}{x_n} \right) \end{vmatrix} < 0.
 \end{aligned}$$

Multiplying the first row by $1/x_n$ and subtracting it from the last, and performing the same operation on the first and the last columns as well, we reduce D to the well known "bordered" determinant F .

$$(15a) \quad F = \begin{vmatrix} 0 & f_1 & f_2 & \cdots & f_n \\ f_1 & f_{11} & f_{12} & \cdots & f_{1n} \\ f_2 & f_{12} & f_{22} & \cdots & f_{2n} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ f_n & f_{1n} & f_{2n} & \cdots & f_{nn} \end{vmatrix} < 0.$$

Thus the second order conditons for the equilibrium of the co-op and of the capitalist firm are the same.

* * *

Since

$$\left(\frac{\partial x_n}{\partial p_n}\right)^* > 0 \quad \text{and} \quad x_n < 0, \quad \frac{\partial x_n}{\partial R} < 0, \quad \text{and} \quad \left(-\frac{\partial x_n}{\partial R}\right) > 0.$$

If x_i is an output and

$$\left(\frac{\partial x_i}{\partial p_n}\right)^* < 0, \quad \frac{\partial x_i}{\partial R} > 0.$$

If x_i is a nonlabor input, the sign of $\partial x_i / \partial R$ depends on whether x_i is complementary to or substitutable for x_n .

3. The Effects of a Change in p_1

Differentiate (2a), (4a), and (5a) in respect to p_1 , and using the same methods as in the preceding section obtain the system of equations

$$\begin{aligned} \sum_1^n f_i \frac{\partial x_i}{\partial p_1} &= 0 \\ f_1 \left(\frac{1}{\lambda} \frac{\partial \lambda}{\partial p_1} \right) + \sum_1^n f_{1i} \frac{\partial x_i}{\partial p_1} &= \frac{1}{\lambda} \\ (20a) \quad f_2 \left(\frac{1}{\lambda} \frac{\partial \lambda}{\partial p_1} \right) + \sum_1^n f_{2n} \frac{\partial x_i}{\partial p_1} &= 0 \\ &\dots \dots \dots \\ f_n \left(\frac{1}{\lambda} \frac{\partial \lambda}{\partial p_1} \right) + \sum_1^n f_{in} \frac{\partial x_i}{\partial p_1} &= -\frac{x_1}{\lambda x_n}, \end{aligned}$$

again based on the matrix given in (15a). Hence,

$$(21a) \quad \frac{\partial x_1}{\partial p_1} = \frac{F_{11}}{\lambda F} - \frac{x_1}{x_n} \frac{F_{1n}}{\lambda F} = \left(\frac{\partial x_1}{\partial p_1}\right)^* - \frac{x_1}{x_n} \left(\frac{\partial x_n}{\partial p_1}\right)^*,$$

$$(22a) \quad \frac{\partial x_n}{\partial p_1} = \frac{F_{1n}}{\lambda F} - \frac{x_1}{x_n} \frac{F_{nn}}{\lambda F} = \left(\frac{\partial x_1}{\partial p_1}\right)^* - \frac{x_1}{x_n} \left(\frac{\partial x_n}{\partial p_1}\right)^*,$$

$$(23a) \quad \frac{\partial x_2}{\partial p_1} = \frac{F_{12}}{\lambda F} - \frac{x_1}{x_n} \frac{F_{2n}}{\lambda F} = \left(\frac{\partial x_1}{\partial p_1}\right)^* - \frac{x_1}{x_n} \left(\frac{\partial x_n}{\partial p_1}\right)^*.$$

By multiplying both sides of expressions (21a)–(23a) by the proper variables, they can be expressed in a more convenient form:

$$(24a) \quad E_{x_1 p_1} = E_{x_1 p_1}^* - E_{x_n p_1}^*,$$

$$(25a) \quad E_{x_n p_1} = \frac{u_1}{u_n} (E_{x_1 p_n}^* - E_{x_n p_n}^*),$$

$$(26a) \quad E_{x_i p_1} = \frac{u_i}{u_2} (E_{x_1 p_1}^* - E_{x_n p_1}^*).$$

It is important to note that $u_i = p_i x_i < 0$ when x_i is an input.

Two assumptions are made here: (1) a given relative increase (or decrease) in all inputs in the twin results in a smaller relative increase (or decrease) in outputs taken as a whole, either because the production function has this attribute throughout the relevant range, or because the firm makes a profit (with $R > 0$) and hence operates to the right of the maximum average product point; (2) the absence of Hicks's "regression," so that $E_{x_i p_j}^* < 0$ if x_i is an output, x_j an input, and $E_{x_i p_j}^* > 0$ if x_i is an input, x_j an output.

Actually, the presence of regression would weaken some results while strengthening others. It does not seem to me that the problem in hand is sufficiently important to warrant additional explorations of cases arising from the great variety of relationships among inputs and outputs possible in a generalized production function (even subject to the constraint given in (15a)). Only the more probable cases are considered here.

(a) *One output, labor the only input.* In (24a), $E_{x_1 p_1}^* < E_{x_n p_1}^*$ because of diminishing returns; therefore, $E_{x_1 p_1} < 0$ and output contracts. So does the labor input.

(b) *One output, several inputs.* The general case is indeterminate. We can establish the sign of $E_{x_1 p_1}$ in (24a) by making the plausible assumption that the isoquants are radially parallel to each other, so that a change in price (p_1) of the output leaves input ratios unchanged, or that $E_{x_i p_1}^* = E_{x_j p_1}^*$ ($i, j = 2, \dots, n$).

From (2a),

$$(27a) \quad \sum_1^n p_i \left(\frac{\partial x_i}{\partial p_1} \right)^* = 0.$$

$$(28a) \quad p_i \left(\frac{\partial x_i}{\partial p_1} \right)^* = p_i \left(\frac{\partial x_i}{\partial p_1} \right)^* \cdot \frac{p_1 x_i}{p_1 x_i} = \frac{u_i E_{x_i p_1}^*}{p_1}.$$

$$(29a) \quad \sum_1^n u_i E_{x_i p_1}^* = 0.$$

If now

$$E_{x_i p_1}^* = E_{x_j p_1}^* = E_{x_n p_1}^* \quad (i, j = 2, \dots, n),$$

$$(30a) \quad u_1 E_{x_1 p_1}^* + E_{x_n p_1}^* \cdot \sum_2^n u_i = 0,$$

$$(31a) \quad E_{x_n p_1}^* = - \frac{u_1 E_{x_1 p_1}^*}{\sum_2^n u_i}.$$

The substitution of (31a) into (24a) gives

$$(32a) \quad E_{x_1 p_1} = \frac{\sum_1^n u_i}{\sum_2^n u_i} \cdot E_{x_1 p_1}^*$$

Now,

$$\sum_1^n u_i > 0, E_{x_1 p_1}^* > 0, \text{ and } \sum_2^n u_i < 0$$

because $x_i < 0$ ($i = 2, \dots, n$). Therefore $E_{x_1 p_1} < 0$.

In (25a) both $E_{x_1 p_n}^* < 0$ and $E_{x_n p_n}^* < 0$, but because of the presence of other inputs (and diminishing returns) $|E_{x_1 p_n}^*| < |E_{x_n p_n}^*|$. It follows that $E_{x_n p_1} < 0$ (because $u_n < 0$).

For the sign of $E_{x_2 p_1}$ in (26a) see section (c-iv) below.

(c) *Several inputs and outputs; x_1 is an output.*

(i) *The sign of $E_{x_1 p_1}$ in (24a).* If x_1 is a very important user of labor, diminishing returns may make $E_{x_1 p_1}^* < E_{x_n p_1}^*$ (though this also depends on the behavior of other inputs and outputs), and $E_{x_1 p_1} < 0$, similar to the two preceding cases. But if x_1 , being one of the several outputs, uses only a moderate part of total labor, then $E_{x_1 p_1}^* > E_{x_n p_1}^*$ and $E_{x_1 p_1} > 0$.

(ii) *The sign of $E_{x_n p_1}$ in (25a).* $E_{x_n p_n}^* < 0$ and, by assumption, $E_{x_1 p_n}^* < 0$. In the presence of other inputs (and diminishing returns), we can expect $|E_{x_1 p_n}^*| < |E_{x_n p_n}^*|$ and $E_{x_n p_1} < 0$. But if wages constitute the major part of the cost of x_1 and if the value of the marginal product in the production of x_1 declines more slowly than in other uses of labor, it is possible that the sign of $E_{x_n p_1}$ may be reversed.

(iii) *The sign of $E_{x_2 p_1}$ in (26a), x_2 being an output.* Let x_2 be at first all other outputs, or the only other output. Assume $E_{x_2 p_2}^* > 0$. If x_1 and x_2 are produced in constant proportions, the result is the same as if x_1 were the only output given in (b) above. If there is some, but not perfect, complementarity between x_1 and x_2 the result is indeterminate unless we assume that all ratios among inputs in the twin remain constant in spite of a change in p_2 , in which case diminishing returns will give $E_{x_2 p_2}^* < E_{x_n p_2}^*$. Since $0 < E_{x_1 p_2}^* < E_{x_2 p_2}^*$, $E_{x_2 p_1} < 0$. If x_1 and x_2 are competing outputs, $E_{x_1 p_2}^* < 0$ and $E_{x_2 p_1} < 0$.

In general, a rise in p_1 is likely to increase the output of x_1 and reduce the input of labor as shown above. Hence a reduction in other outputs taken as a whole is highly probable.

If x_2 is one of several outputs and is competitive with x_1 , $E_{x_2 p_1} < 0$. Otherwise, the result is indeterminate.

(iv) *The sign of $E_{x_1 p_1}$ in (26a), x_2 being an input.* Assume $E_{x_1 p_2}^* < 0$. If x_2 is highly complementary with x_n , it is likely (but not certain) that $|E_{x_1 p_2}^*| < |E_{x_n p_2}^*|$ and $E_{x_1 p_1} < 0$. If the complementarity is slight, the result is indeterminate. If x_2 and x_n are substitutes, $E_{x_n p_2}^* > 0$ and $E_{x_2 p_1} < 0$.

(d) *Several inputs and outputs: x_1 is an input.*

(i) *The sign of $E_{x_1 p_1}$ in (24a).* Here $E_{x_1 p_1}^* < 0$. If there is some complementarity between x_1 and x_n , $|E_{x_1 p_1}^*| > |E_{x_n p_1}^*|$ and $E_{x_1 p_1}^* < 0$, unless they are used in constant proportions, in which case $E_{x_1 p_1} = 0$. If x_1 and x_n are substitutes, $E_{x_1 p_1}^* > 0$ and $E_{x_1 p_1} < 0$.

(ii) *The sign of $E_{x_n p_1}$ in (25a).* Here $E_{x_1 p_1}^* < 0$. With some complementarity between x_1 and x_n , $|E_{x_1 p_1}^*| < |E_{x_n p_1}^*|$ and $E_{x_n p_1} > 0$. If they are substitutes, $E_{x_1 p_1}^* > 0$ and again $E_{x_n p_1} > 0$. Only when x_1 and x_n are used in constant proportions $E_{x_n p_1} = 0$. So the increase in the price of any nonlabor input, even when complementary with labor, increases the use of labor (except for constant proportions).

(iii) *The sign of $E_{x_1 p_1}$ in (26a), x_2 being an output or an input.* Unless specific assumptions are made about the interrelationships among the variables involved, the result is indeterminate.

* * *

A comment on the effects of the magnitude of R on $E_{x_1 p_1}$ and $E_{x_n p_1}$ in (24a) and (25a). Since $p_n = v$, we obtain from (1a)

$$(33a) \quad p_n x_n = - \left(\sum_1^{n-1} p_i x_i - R \right).$$

Differentiating both sides of this expression in respect to p_1 and taking advantage of

$$\sum_1^n p_i \frac{\partial x_i}{\partial p_1} = 0$$

in equilibrium [3, p. 615], we find that

$$(34a) \quad \frac{\partial p_n}{\partial p_1} = - \frac{x_1}{x_n},$$

and therefore

$$(35a) \quad \frac{\partial p_n}{\partial p_1} \cdot \frac{p_1}{p_n} = \frac{p_1 x_1}{\sum_1^{n-1} p_i x_i - R}.$$

Thus a larger R makes p_n more sensitive to a rise in p_1 and hence causes a greater reduction in labor input in response to a given rise in p_1 . So $|E_{x_n p_1}|$ is increased. But on $E_{x_1 p_1}$ in (24a) R does not have a clear effect, because a large R implies a small payroll for the twin and a reduction in the importance of labor cost. It is possible that the magnitude of R has no effect on $E_{x_1 p_1}$ at all, and this is indeed the case with a Cobb-Douglas production function consisting of one output and of several inputs, and subject to decreasing returns to scale.

MEASUREMENT OF POTENTIAL OUTPUT

By EDWIN KUE*

Ever since the *General Theory* first appeared, economists and policy-makers have been concerned with measuring full employment by adjusting official labor force statistics to a norm that would satisfy theoretical and practical notions of full employment.

A twin concept, potential (aggregate) output attainable at full employment, is related to the fully employed labor force through a production function. While the greater complexity of the potential output concept has restricted most discussion to hypothetical textbook examples, it has recently become a part of the Council of Economic Advisers' [5] [7] aggregative analysis. Current interest in growth models has also led to measurement of potential output [12] [19] [25].

In this paper a structural method for estimating potential output is presented and compared with two alternative techniques; the main elements of this subsystem include a production function, a labor force participation equation, and a policy restriction which stipulates that unemployment shall be, for example, 4 per cent (or 3 per cent, or . . .).¹ Labor participation rates increase when employment opportunities are good and decline when employment drops, according to studies by Bowen and Finegan [3], Lebergott [17], Mincer [18], Strand and Fernburg [26], and Tella [27].

I. *Measuring Potential Output with Cyclical Data*

Dynamic Production Functions

Estimates of production functions from data subject to cyclical fluctuations pose severe practical problems. It has been widely observed [1] [5] [9] [11] [13] [14] [22] that average labor productivity falls when output declines and rises when output rises, contrary to the usual

* The author is professor of economics and finance at Massachusetts Institute of Technology. Helpful comments on an earlier draft were made by A. Okun, R. M. Solow, and M. Spiro. Research support by the Ford Foundation to the Sloan School of Management and the Economics Department is gratefully acknowledged. The author is also indebted to the National Science Foundation's grant to the Economics Department. Peter Hughes provided valuable research assistance.

The general analytic approach is similar to that of Locke Anderson and Jarvis Babcock. Their emphasis, which is on closing "the" gap, is different from mine. There are clear differences in their formulation of the behavior equations which lead to significantly different policy implications. W. A. W. Godley and J. R. Shepherd [8] have applied a related approach to the British economy. Their treatment of labor supply is more elaborate in some important respects, but slurs over direct estimation of participation rates by relating potential output to unemployment.

short-run theory of diminishing returns (average or marginal, but certainly the latter). While various explanations can be adduced to explain this behavior, one important cause is the lagged response of employment to short-run variations in output. This phenomenon is especially evident in nonproduction-worker employment, since much of this "overhead" personnel is associated with management, supervision, and other tasks which will not be rapidly adjusted to what are deemed to be only temporary fluctuations in labor requirements. Production cost changes in the spirit of production, inventory, and employment-smoothing suggested by optimizing linear decision rules [10] [23] similarly imply lagged adjustments of employment to output changes. A second significant possibility is that of increasing returns to scale over broad ranges of output. While it would be a mistake to rule out this possibility altogether (and several others discussed elsewhere [14] [15]), empirical evidence points to the lagged adjustment of employment to output as the single most important short-run element.

One simple dynamic production function that reflects these employment lags can be represented in the following way:

$$(1) \quad X_t = \beta_0 + \beta_1 X_{t-1} + \beta_2 E_t + \beta_3 E_{t-1} + \beta_4 t + \beta_5 K_{t-1} + \epsilon_t,$$

where X is output, E is employment, K is capital stock, t is a time trend, and ϵ the regression-error term.

The steady-state solution of (1) (where a bar represents a fixed value) is:

$$(2) \quad \bar{X} = \frac{\beta_0}{1 - \beta_1} + \frac{\beta_2 + \beta_3}{1 - \beta_1} \bar{E} + \frac{\beta_4}{1 - \beta_1} \bar{t} + \frac{\beta_5}{1 - \beta_1} \bar{K}.$$

This is a linear approximation to some unknown production relation in which output is a function of the usual inputs, capital and labor, plus a trend term to represent disembodied technical change.² The initial effect of an increase in employment reflected in β_2 will naturally be positive. When the employment response is rapid, the coefficient of lagged employment, β_3 , will be negative; on this account the intermediate and longer-run elasticities of output (two or more quarters) with respect to labor input will be lower than the impact, one-quarter elasticity.

One modification of equation (1) will be made in the empirical estimates. The capital stock term has been dropped from the estimated equations that are presented, because of collinearity with trend and the inferior quality of measured aggregate capital stock. Since investment is partly the vehicle for technical change [19] [21] [25], this deficiency should be remedied for *ex ante* policy calculations. However, this neglect does not preclude the calculation of historical gaps or the demon-

² When data are logarithms, we once more have the Cobb-Douglas function.

stration of the main methodological points. Furthermore, Solow [24] has shown that if production were to take place under a regime of (*ex post*) fixed proportions, and if there is more than enough capital to match with the existing labor supply, technical change represented by trend should appear in the production function, but capital would not.

B. Empirical Estimates

The largest output aggregate that seems appropriate for production-function estimation, called Gross Business Product, is measured by constant-dollar GNP, exclusive of outputs that are not related to inputs in the usual spirit of a production function. One obvious example of such exceptions would be imputed rents on owner-occupied dwellings. Similarly, the government, households and institutions, and rest-of-world sectors have been excluded. Agriculture has also been left out because labor input and labor supply measurement problems are complicated by the extent of secondary family workers. Gross Business Product comprises about 73 per cent of GNP.

A logarithmic version of equation (1) has two advantages over the arithmetic linear approximation: an exponential trend would imply a more rapid increase in potential output toward the end of the period than the linear relation and, in addition, it will be consistent with the view that labor's marginal productivity is an increasing function of time. Both propositions are theoretically preferable.³

$$\begin{aligned} \log X_t = & \underset{(.00038)}{.00158} \text{ TIME} + \underset{(.262)}{1.808} \log E_t - \underset{(.208)}{1.534} \log E_{t-1} \\ & + \underset{(.115)}{.667} \log X_{t-1} + \underset{(.406)}{.814} \\ (3) \quad \bar{R}^2 = & .987 \quad \bar{S}_e = .0140 \quad \text{D.W.} = 2.044 \end{aligned}$$

Fitted to quarterly data 1949-II to 1962-IV.

The corresponding steady-state solution:

$$(4) \quad \log X_t^* = .0190 \text{ TIME} + .823 \log E_t^* + 2.442.$$

One other theoretical and econometric aspect, the structural source of the distributed lag, needs further consideration. In full generality, distributed lags in both output and employment could be "caused" by employment lagging output, output lagging employment, or both. This is a matter of some relevance, since which variable will be considered as dependent, and which the forcing function, will be determined by the choice.⁴

³ To conserve space, linear estimates are not presented. Where the results differed, the logarithmic version seemed most reasonable.

⁴ Estimates with employment the dependent variable were made, and the resultant steady-state solution solved for output as the left-hand side variable. Potential output estimates were

Industries which have a substantial reservoir of underutilized labor will tend to have employment lag behind output, so that if output increases, employment levels will be gradually adjusted to the new higher level. If, on the other hand, there is only negligible slack in the labor supply, output changes must lag behind changes in employment, at least when output is increasing. Finally, where in-process inventory is large relative to the production rate, the more likely it is that output will lag behind employment. Shipbuilding provides a clear-cut example of this latter phenomenon. Because this matter cannot be settled readily at an aggregate level, requiring as it does a detailed understanding of industry structure, I shall only report results for production functions estimated with output as the dependent variable.

The response of output to labor input in equation (3) for various periods of time has been summarized in Table 1. The impact elasticity of output with respect to employment is about 1.80, a magnitude that will reappear later on when comparing this approach with several others. The cumulative two-quarter elasticity is much closer to the long-run steady-state elasticity. When the output-employment adjustment is completed, the elasticity declines sharply to .82, a magnitude that is clearly consistent with constant returns, but which does not imply this regime.⁵ This illustrates the obvious pitfall of using cyclical data which do not explicitly include an appropriate lag structure. My own analysis for measuring the output gap uses only the steady-state solution of equation (4) to measure potential output.

II. *Labor Participation Equations*

Within the past five years, the sensitivity of the labor force to employment opportunities has become widely recognized; it seems that for about each additional worker fired during a slump, two workers leave the labor force. Thus unemployment increases by half as much as the decrease in employment. Women, young men, and older men are the most sensitive to labor market opportunities in the manner suggested, which has come to be known as the "discouraged worker" hypothesis.

An alternative hypothesis asserts a contrary tendency, on the grounds that secondary family workers will enter the labor market when primary workers lose their jobs, to offset the income losses thus incurred. The dominant gross relation clearly supports the "discouraged worker"

typically about \$5-\$10 billion higher in this form. With few exceptions, potential output gaps (for a given participation equation) were smallest for output dependent variable linear form and then, in ascending order, output dependent variable, log form, employment dependent variable linear form, employment dependent variable, log form.

⁵ A more complete treatment and discussion of these phenomena in their most relevant context can be found in E. Kuh [14]. Strong possibilities of increasing returns to scale are implied by the analogous estimates for the manufacturing sector.

TABLE 1—CUMULATIVE ELASTICITY OF OUTPUT
WITH RESPECT TO EMPLOYMENT^a

Period	Current	1st Quarter	2nd Quarter	Long Run
Elasticity	1.81	1.48	1.27	.82

^a These elasticities show the cumulative per cent output response to a steadily maintained 1 per cent increase in the level of employment.

hypothesis according to the Bowen and Finegan [3] cross-section study, and the most immediately relevant time-series estimates by Lebergott [17], Tella [27], and Strand and Dernberg [26]. I have chosen variants of the Tella relation over the preferred relation of Strand and Dernberg, although the different authors are in general agreement on much of the basic analysis.⁶

The participation equations chosen for subsequent analysis relate the labor force participation rate primarily to employment divided by population. In addition, either the reciprocal of population (a trend-like variable) or the lagged dependent variable has been included. The latter variable should reflect the lagged response of participation to variations in the employment-population ratio.

$$(5a) \quad \left(\frac{L}{P}\right)_t = \alpha_0 + \alpha_1 \left(\frac{E}{P}\right)_t + \epsilon_{1t},$$

$$(5b) \quad \left(\frac{L}{P}\right)_t = \alpha'_0 + \alpha'_1 \left(\frac{E}{P}\right)_t + \alpha'_2 \left(\frac{L}{P}\right)_{t-1} + \epsilon_{2t},$$

$$(5c) \quad \left(\frac{L}{P}\right)_t = \alpha''_0 + \alpha''_1 \left(\frac{E}{P}\right)_t + \alpha''_2 \frac{1}{P_t} + \epsilon_{3t}.$$

E is employment for individuals 14 years and over in the business sector; P is civilian noninstitutional population 14 years and over; L , the labor force associated with the business sector, includes the unemployed with previous experience in the business sector as well as workers with no previous experience. The variables appear in ratio form because collinearity among the explanatory variables prevents sensible estimates in undeflated form. Since the deflator is approximately linearly and homo-

⁶ Strand and Dernberg [22] have also included a variable intended to measure the secondary worker hypothesis. This variable is the ratio of unemployment benefit exhaustions to unemployment for the period two months in the future beyond the current-period participation rate dependent variable. This ingenious representation substantially increases the amount of variation explained and is highly significant statistically, both for the aggregate and in separate regressions for different age-sex groups (in a presently unpublished paper). It seems reasonable to avoid a strong commitment to this formulation because of its proxy nature, despite the impressive statistical performance. This construction has been sharply criticized by Mincer [18].

geneously related to the labor force and employment over periods of the length considered, significance tests will not be biased on this account [16].⁷

Separate participation responses by various age-sex categories represent a clear improvement over these global estimates [28], but the basic objective of this paper is well enough served by the aggregate equations.

Variable	Definition	Mean
E/P	employment to population ratio	.3464
L/P	labor force to population ratio	.3719
$1/P$	inverse of population	.0082

(6a)

$$\left(\frac{L}{P}\right)_t = .283 + .257 \left(\frac{E}{P}\right)_t$$

(.031) (.090)

$\bar{R}^2 = .158 \quad \bar{S}_e = .0037 \quad \text{D.W.} = .347$

(6b)

$$\left(\frac{L}{P}\right)_t = .047 + .123 \left(\frac{E}{P}\right)_t + .760 \left(\frac{L}{P}\right)_{t-1}$$

(.035) (.057) (.094)

$\bar{R}^2 = .693 \quad \bar{S}_e = .0022 \quad \text{D.W.} = 1.35$

(6c)

$$\left(\frac{L}{P}\right)_t = .292 + .385 \left(\frac{E}{P}\right)_t - 6.524 \left(\frac{1}{P}\right)_t$$

(.027) (.086) (1.811)

$\bar{R}^2 = .364 \quad \bar{S}_e = .0032 \quad \text{D.W.} = 0.47.$

Period of fit for three equations is 1953-III through 1962-IV.

Estimates of the participation response to employment vary considerably, depending upon which formulation is chosen. The slope of .26 in equation (6a) contrasts sharply with that of .38 in equation (6c), which includes the trend representation of $1/P_t$, and the steady-state response of .50 from equation (6b). Statistical properties of the last two equations are superior to those of the first, although much variance remains unexplained and first-order serial correlation is substantial, suggesting perhaps that the short-run dynamics have not been properly specified. Readers are referred to the basic research cited, to which full justice has not been done here. Nevertheless, it seems that further investigation is required before much confidence can be placed in any particular param-

⁷ Anderson and Babcock [1], unlike Strand and Dernberg, and my own treatment, included armed forces in labor force and employment. I have not done so, since participation rates behaved in an unusual manner during Korea and there is no reason to expect similar behavior to prevail in time of peace. Therefore, the participation regressions were fitted from 1953-II until 1962-IV. Inclusion of armed forces after 1953 would have little effect on the estimated slope parameters.

eter estimate. The policy implications of the alternative participation equation forms for potential output differ significantly. This does not impede their usefulness in illustrating the methods developed in this paper. Mincer [18] suggests that an upward bias might exist in the time-series estimates. The smallest participation response, that recorded in (6a), could be viewed as least subject to bias when results are evaluated. Because this estimate neglects lagged responses, however, one might just as readily conceive that this opposite bias dominates.⁸

III. *The Full-Employment Gap*

Having estimated a production function and several participation equations, all that remains is to combine them in a relevant manner. The full-employment-policy restriction, equation (8), and one participation equation (for example, the linearized version of equation (5a) represented here as equation (7)), are solved simultaneously:

$$(7) \quad L_t^* = \beta_1 P_t + \beta_2 E_t^* + \nu_t$$

$$(8) \quad E_t^* = \lambda L_t^*$$

Substituting equation (7) into equation (8) yields equation (9):

* Partial coverage of the labor force (the government sector, agriculture, and some services are excluded) might prove to be a serious shortcoming of the entire analysis. Several circumstances mitigate this defect. First, the estimated parameters when adjusted for coverage, are not greatly different from those obtained for the entire labor force. Second, coverage is a substantial 69 per cent of the total, so that intrasectoral movements are likely to dominate intersectoral movements. As a particular sector becomes a smaller fraction of the total labor force, however, calculations of this character become increasingly suspect.

Using seasonally adjusted quarterly data and Civilian Labor Force data instead of the sub-sector labor force yielded the following results that can be compared with those in the text, and the nearly equivalent formulation of Strand and Dernberg.

$$(a) \quad \left(\frac{L}{P}\right)_t = .335 + .421 \left(\frac{E}{P}\right)_t$$

(.039) (.074)

$$\bar{R}^2 = .387 \quad \bar{S}_e = .0046 \quad \text{D.W.} = .38$$

$$(b) \quad \left(\frac{L}{P}\right)_t = .075 + .195 \left(\frac{E}{P}\right)_t + .680 \left(\frac{L}{P}\right)_{t-1}$$

(.044) (.059) (.092)

$$\bar{R}^2 = .722 \quad \bar{S}_e = .0031 \quad \text{D.W.} = 1.82$$

$$(c) \quad \left(\frac{L}{P}\right)_t = .310 + .523 \left(\frac{E}{P}\right)_t - 3.431 \frac{1}{P_t}$$

(.043) (.099) (2.259)

$$\bar{R}^2 = .414 \quad \bar{S}_e = .0046 \quad \text{D.W.} = .39$$

Period of Fit: 1954-I to 1959-IV.

An upward bias arising from common sampling errors in labor force and employment data should also be mentioned. Its magnitude is likely to be small (about .02, with a maximum of .045) at existing levels of sampling error, so that further adjustment on this account seems needless.

$$(9) \quad E_t^* = \frac{\lambda \beta_1}{1 - \lambda \beta_2} P_t.$$

This full-employment labor quantity is then substituted into the steady-state production function, equation (10),

$$(10) \quad \log X^* = \alpha_1 \log E^* + \alpha_2 t + \alpha_3,$$

which provides an estimate of full employment or potential output.

The full-employment parameter λ requires comment. It has been chosen by the Council of Economic Advisers to be .96 as a provisional policy objective:

The Council's estimate of Potential GNP reflects the belief that the economy could operate at a 4 per cent unemployment rate today without substantial strains on either labor supplies or plant capacity [7, p. 83].

The Council's choice of $\lambda = .96$ is stated to be "an interim target" [7, p. 81]. Evidently, this concept of full employment depends, as in all good sense it must, on considerations other than maximum attainable output. In particular, it appears to embody a widely held political and economic judgment that with existing wage-price behavior relations and balance-of-payments problems, undesirable inflation might ensue if unemployment were to drop below 4 per cent for an extended period. I shall adhere to this 4 per cent convention in order to make comparisons with the Council's analysis and other similar calculations.

Because the business sector data are not directly comparable with the Council's GNP gap figures, a rough attempt has been made to remedy this deficiency. The procedure is decidedly crude, so that the resulting comparisons should be treated with appropriate reserve. Since most slack occurs in the business sector (government, domestic service, and agriculture, in particular, not being prone to cyclical disturbances), the strong assumption was made that *all* slack exists in the business sector, so that actual nonbusiness sector output is assumed equal to its potential output. On this basis, columns (4)–(6) of Table 2 were derived from the data underlying columns (1)–(3). Chart 1 portrays derived GNP output gaps for columns 4 through 6.

The more conservative output gaps are based on participation equations (6a) and (6c), while participation equation (6b), including the lagged dependent variable, indicates slightly larger gaps than the others. Generally speaking, the business sector gaps are larger than the Council gaps, shown in column (7), a partly fictitious result that to some extent has been counteracted by the Derived GNP gap calculations. In the 1954 recession the Derived GNP gaps were similar to the Council gap. During the period 1955-I/1962-II the CEA gap is consistently larger

TABLE 2—OUTPUT GAPS AS PER CENT OF POTENTIAL OUTPUT

than the more conservative Derived gaps. The paths during the 1958 recession are highly similar although, in the 1958–59 recovery phase, my results would indicate that the gap had been largely eliminated while the Council gap never dropped below 3 per cent. When production functions using employment as the dependent variable are used to estimate Derived gaps (see footnote 4), the difference between Council gaps and Derived gaps disappeared. Since my own estimates are open to numerous valid objections, a definitive resolution of these differences must await later research results. Less highly aggregated production functions will surely be an indispensable element of more refined estimates.

IV. *Different Measures of Output and Employment Gaps*

A. *The Council of Economic Advisers*

While the Council of Economic Advisers uses economic analysis of production relations, they have also relied on an estimated exponential trend as a smoothing device to provide a quantitative summary of the main underlying economic determinants. An important element in the underlying calculation is the empirical generalization that “each percentage point of progress toward 4 per cent in the unemployment rate has meant a gain of roughly 3 per cent in total output in postwar periods of expansion” [6, p. 50]. About two-fifths of the output gap would be closed by lower unemployment and one-tenth by a larger labor force, in recognition of the participation response already discussed.

CHART 1. OUTPUT GAPS AS PER CENT OF POTENTIAL OUTPUT

The remaining half of the gap would have been closed, according to an early Council calculation [6], two-fifths by an improvement in productivity and one-tenth by longer hours per worker at higher utilization rates. The assumed short-run elasticity of output with respect to employment is about three. This accurately reflects short-run responses that are so important in assessing alternative paths to full employment, but apart from some permanent economy of scale gains, much of the productivity gain imputed to higher utilization would have disappeared in the new, steady-state full-employment equilibrium.⁹

B. Okun Formulation

The pathbreaking article of Okun [20] sought to take account of all the influences that have been mentioned by directly linking output to unemployment:

Ideally, the measurement of potential output would appraise the various possible influences of high employment on labor input and productivity and evaluate the influences step-by-step, developing quantitative estimates for each adjustment to produce the desired measure of potential. While I shall discuss the steps individually below, the basic technique I am reporting consists of a leap from the unemployment rate to potential output rather than a series of steps involving the sev-

⁹ Without investigating the point here, I suspect that some component of the longer hours per worker would vanish in a new higher employment steady state, since variations in hours are a dominant method of adjusting labor input to temporary variations in output. This aspect of hour behavior has substantial econometric support [15].

eral underlying factors. Strictly speaking, the leap requires the assumption that, whatever the influence of slack economic activity on average hours, labor force participation and manhour productivity, the magnitudes of all these effects are related to the unemployment rate. With this assumption, the unemployment rate can be viewed as a proxy variable for all the ways in which output is affected by idle resources [20].

Three alternative methods of relating unemployment to output lead Okun to the view that "the uniformity which emerged from these various techniques was the approximate 3-to-1 link between output and the unemployment rate."

It also turned out that a graph of potential GNP embodying this relation leads to "a curve that wiggles from quarter-to-quarter, even dipping at times." Okun prefers a $3\frac{1}{2}$ per cent per year growth trend since he finds it "difficult to accept the verdict that potential output has actually contracted at times, as the unsmoothed unemployment measure implies."

Finally, Okun states that "the record clearly shows that manhour productivity is depressed by low levels of utilization and that periods of movement toward full employment yield considerably above-average productivity gains." This leads to a correct inference that "the positive relationship between output and labor productivity suggests that much of labor input is essentially a fixed cost for fairly substantial periods."

It seems that the short-term irregularities (which Okun quite properly rejects as an accurate reflection of potential output) and the high short-run elasticity of output with respect to unemployment are both reflections of the short-run distributed-lag relation between output and employment, which can be eliminated efficiently at the source by placing direct reliance on the steady state solution of the cyclical production function recommended in the preceding section of the paper.

C. Labor Gaps

It is a matter of some interest to estimate unemployment by subtracting actual employment from potential (rather than actual) labor force. Table 3 contains unemployment gaps for each of the three participation equations for the business sector and the Strand-Dernberg calculation for total civilian labor force, after adjusting actual to potential labor force at a 4 per cent unemployment rate. Chart 2 illustrates potential gaps for employment and output based on the most conservative labor participation equations (6a).¹⁰ In each recovery the output gap declines

¹⁰ The Strand-Dernberg estimates are well below my most "conservative" participation equations (6a) and (6b) throughout most of the period, in part at least because of different coverage, until 1961-IV when their estimate just exceeds the (6a) level. Their calculation depends only on an estimate of population growth, and an additional equation to explain the additional variable related to the secondary worker hypothesis. A production function by-passed completely.

TABLE 3—UNEMPLOYMENT PERCENTAGE GAPS

before the employment gap, reflecting the employment-output lag which has been repeatedly emphasized throughout this paper. It furthermore appears that at times actual output exceeds long-run steady-state potential output even when the potential unemployment gap is in excess of 4 per cent. Since the parameters are sufficiently uncertain, and the capacity concept itself is somewhat ambiguous, literal insistence on inadequate capacity would be unwarranted.

In order to focus more closely on differences among the participation equations, the three potential unemployment gaps have been plotted together on Chart 3. Equation (6b) has the highest gap throughout, although from 1958 on it is virtually indistinguishable from (6c). Since this formulation is the only one which begins to measure lagged responses, however simply, it does not appear wise to dismiss it out of hand. On theoretical and statistical grounds, equations (6b) or (6c) seem superior to (6a), but a final choice does not seem possible on the basis of the evidence presented here.

CHART 2. POTENTIAL UNEMPLOYMENT AND POTENTIAL OUTPUT GAP PERCENTAGES
[Based on participation equation (6a)]

CHART 3. ALTERNATIVE EMPLOYMENT GAPS

V. Summary and Qualifications

This paper provides an outline of operational procedures for measuring potential output, a useful conception for short- and intermediate-run fiscal and monetary policy measures. Predominant emphasis has been on the measurement of potential output, rather than the corollary endeavor of using this equation system to trace out paths from underutilization toward potential output.¹¹

The empirical bases of these parameters are shaky enough so that excessive confidence ought not to be placed on the present set of point estimates which, however, seem solidly enough based to illustrate an appropriate set of procedures. While existing research on cyclical participation rates has offered valuable new insights, continued efforts seem required in order to narrow the range of plausible estimates of potential labor force.¹² Furthermore, the highly aggregated cyclical production function ought to be replaced by a more disaggregated set of relations. These should include capital stock and reflect different dynamic reactions among industries and possibly among different types of labor inputs. Explicit consideration of cyclical variations in hours worked should also be included in future calculations.

Various methods have recently been proposed to estimate output that could be produced at a given level of unemployment. These methods include quite mechanical (though pragmatically useful) trend extrapolation and relating current unemployment to current output. The method suggested here combines recent econometric developments in the estimation of labor participation rates and cyclical production functions to portray the major elements that should appear in a proper structural formulation.

DATA APPENDIX

Gross Product Originating in the Business Sector in 1954 Dollars: By Quarters at Annual Rates

The original data were presented in an article by M. L. Marimont, "GNP

¹¹ The latter problem is in essence an exercise in simulation, since: (a) the initial conditions relating to output and employment, and (b) subsequent feasible and/or desired levels of output (obtainable through fiscal and monetary policy), in principle are consistent with an indefinitely large number of intermediate-output, employment configurations. Optimal macroeconomic decision rules might readily be applied to provide a more restricted (possibly unique) set of choices. At a future date, it should be worthwhile to carry out some of the more interesting combinations, within the subsystem and in the context of a complete equation system such as the Brookings-SSRC econometric model [4].

¹² Tella [28] and Strand and Dernberg have done additional work (published in this *Review*, March 1966) on age-sex participation rate responses, which lend support to their more aggregative results previously cited. Two important aspects of the problem not yet solved are, first a more precise characterization of the lag structure; and second, the cross-elasticities of supply among the different age-sex groups.

by Major Industries," *Survey of Current Business*, October 1962, pages 6-18. Comprehensive annual data by originating sector were here presented for the first time. These data have been interpolated on a quarterly basis with relevant quantity indices (including components of the Federal Reserve Board Index of Industrial Production for Manufacturing) by Gary Fromm and James Craig for the Brookings-SSRC Econometric Model Project.

The gross product originating series was arrived at (to within the statistical discrepancy published by Marimont) by aggregating the business industries and adding actual deflated residential rents¹³ (thus excluding imputed rent on owner occupied dwellings). Quarterly data on the business industries, including manufacturing, construction, trade, transportation, public utilities and mining, had already been constructed by the Brookings-SSRC Econometric Model Project. Annual real residential rents were constructed using a quadratic interpolation formula and then added to the business industries to form the business sector gross product originating.

Employment and Labor Force by Quarters in the Business Sector

The data for employment and labor force associated with the business sector have been computed and seasonally adjusted by the Bureau of Labor Statistics. Both the household and establishment surveys of labor force and employment have been used in preparing these estimates. Employment in the business sector is approximated by subtracting the number of wage and salary workers in government from the nonagricultural employment excluding domestics.¹⁴ To obtain the labor force associated with the business sector, those unemployed with previous experience in the business industries, and those unemployed with no previous experience are added to the employment totals previously described.

Civilian Population by Quarters

Monthly statistics on the civilian noninstitutional population over the age of 14 series are regularly published by the Bureau of Labor Statistics. Quarterly data were compiled by averaging the three constituent midmonth figures, and then seasonally adjusting this series using standard constant seasonal adjustment factor methods. The 1949 and 1951 quarterly data (used only in extrapolation backwards of equations (6a) and (6c)) were adjusted upwards to be comparable with data based upon the 1960 census.

OWNERSHIP AND CONTROL IN THE 200 LARGEST NONFINANCIAL CORPORATIONS, 1929 AND 1963

By ROBERT J. LARNER*

In 1932, Adolf Berle and Gardiner Means published their classic study, *The Modern Corporation and Private Property*, a major thesis of which was that "Ownership of wealth without appreciable control and control of wealth without appreciable ownership appear to be the logical outcome of corporate development" [4, p. 69]. Since then, the existence of management control among giant corporations and its increasing extent over time have been generally accepted in the literature as part of the "conventional wisdom" [2, pp. 70-74] [3, p. 30] [5] [7] [13, p. 53]. Yet, with the exception of the 1939 study which the Securities and Exchange Commission prepared for the Temporary National Economic Committee [18], no attempt seems to have been made to determine the extent of management control in the years since the Berle and Means study.

This article attempts to measure systematically the extent to which management control actually exists among the 200 largest nonfinancial corporations in the first half of the 1960's. The article is divided into two parts: the first part describes the method followed in the study, and the second summarizes the results of the study and compares them with the findings of the 1929 Berle and Means study.

I. *The Method of This Study*

To assure as direct a comparison as possible between the 1929 and the 1963 findings, this paper will follow very closely the definitions, procedures, and classifications used in the Berle and Means study. Since direction over the activities of a corporation is legally and theoretically exercised by its board of directors, Berle and Means defined control as the "... actual power to select the board of directors (or its majority)" [4, p. 69]. Although the power to control and the actual exercise of that power can conceivably reside in different individuals, there are nevertheless cogent reasons for accepting Berle and Means's definition of control. First, even if the owner of a majority or substantial minority of a corporation's voting stock were to surrender control to the manage-

* The author is a graduate student in economics at the University of Wisconsin. He wishes to thank Professor Leonard Weiss of that university for the encouragement, advice, and overall supervision he has so kindly given in the preparation of this article, an earlier draft of which was written for his seminar in industrial organization. The author, however, is solely responsible for all errors. Part of the research was financed by the National Science Foundation.

ment, he would still retain the legal power to vote an unsatisfactory board of directors out of office, and even such a dormant power can be a strong influence. Secondly, to prevent biased results which are solely dependent on arbitrary judgements, it seems wise to use objective criteria which are easily observed and capable of precise measurement in determining the type of corporate control.

Berle and Means distinguished between "ultimate control" and "immediate control." This distinction occurred where one corporation controlled another through a dominant minority stock interest.¹ In this case, the controlled corporation was always classified as immediately controlled by either minority or joint-minority interests. If the controlling corporation itself was management-controlled, then the controlled corporation was also classified as ultimately controlled by management. If the controlling corporation was not management-controlled, then the controlled corporation was said to be ultimately controlled through pyramiding. The present study also uses this distinction.

Following Berle and Means, our list of the 200 largest nonfinancial corporations is composed of firms primarily engaged in manufacturing, mining, merchandising, transportation, and electric, gas, and pipeline utilities. Banks, insurance companies, and investment companies are excluded. Size is measured in terms of book assets, a procedure which overstates the size of the transportation and utility companies relative to the size of firms in other industries. The use of sales to measure size, however, would introduce an equally serious opposite bias.² Moreover, since Berle and Means, the SEC study [18], and R. A. Gordon [6] all used assets to measure size, this paper will follow the same procedure to maintain comparability.³

Berle and Means classified the firms in their study according to the following five types of corporate control: (1) privately owned, (2) con-

¹ In the Berle and Means study, a corporation which was majority-controlled by another corporation was classified as a subsidiary of the latter and was disregarded, except where an important element of pyramiding entered in. The present study follows the same procedure, except where the controlling corporation is a smaller firm not included among the "200 largest." In this case the controlled corporation is retained as if it were an independent company: e.g. Hughes' Tool Co. is ignored and TWA is treated as majority-controlled. If the controlling corporation is a foreign firm, no attempt is made to determine if the foreign firm is management-controlled, and the controlled corporation is assigned either to ultimate minority control or to ultimate control through pyramiding. This is the same procedure which Berle and Means followed.

² Perhaps the best measure of size is value added, since it compares the value of the factors of production controlled by each firm [1], but data on value added by firm are not generally available.

³ The names and assets of the 200 largest nonfinancial corporations in 1963 appear in the appendix to this article, which may be obtained from the author on request. Requests can be addressed in care of the Department of Economics, University of Wisconsin, Madison, Wisconsin 53706.

trolled through the ownership of a majority of the voting stock, (3) controlled through the ownership of a dominant minority of the voting stock, (4) controlled by means of a legal device,⁴ and (5) management-controlled.⁵ This study uses the same categories.

A firm is considered to be privately owned if an individual, a family, or a group of business associates holds 80 per cent or more of its voting stock. For majority ownership, the individual, family, or group of business associates must own between 50 and 80 per cent of the voting stock. In the Berle and Means study, stock ownership of between 20 and 50 per cent was generally necessary for minority control, although in several specific instances a smaller holding was credited with the power of control. In view of the greater size of the 200 largest nonfinancial corporations in 1963 and the wider dispersion of their stock, this lower limit to minority control seems too high. In the present study a firm is classified as immediately controlled by minority stock ownership if 10 per cent or more of its voting stock is held by an individual, family, corporation, or group of business associates.⁶

Berle and Means assigned corporations in which no base of control in stock ownership could be found to management control on the belief that no group of stockholders would be able under ordinary circumstances to muster enough votes to challenge the rule of management. This study follows the same procedure.⁷

When all of the above criteria are applied to the 1963 data, it is generally not difficult to distinguish management control from the other types of control, but several errors or distortions occur when ownership control is further broken down into privately owned, majority-controlled, and minority-controlled corporations, and those controlled through a legal device.⁸

⁴ Berle and Means recognized four kinds of legal devices by which corporate control might be obtained: (1) pyramiding, (2) nonvoting common stock, (3) stock with disproportionate voting power, and (4) the voting trust. Only the first and the fourth devices are found today.

⁵ For a more detailed description of these five categories and of the criteria for each, see Chapter 5 in *The Modern Corporation and Private Property* [4].

⁶ In two cases, this rule has been disregarded. The Transcontinental Gas Pipe Line Company is classified as management-controlled even though the Stone & Webster Company holds of record an 11 per cent stock interest, since the latter is not represented on Transcontinental's board of directors. On the other hand, May Department Stores Company is classified as minority-controlled even though the May family has only a 3.9 per cent stock interest, since members of the May family hold the offices of chairman, vice-chairman, and president, and occupy five seats on the board of directors.

⁷ In addition, Berle and Means found 16 companies to be controlled jointly, either by two or more minority interests or by a minority interest and management. In the latter case, they divided the corporation into two "half companies," each possessing one-half of the assets of the original company. One of these "half companies" was then classified as management-controlled and the other as minority-controlled. This joint minority-management control category is not used in the present study.

II. *Summary and Comparison of the Results*

Each of the 200 largest nonfinancial corporations in 1963 is listed in the appendix, together with its size and rank in assets, its type of control, immediate and ultimate, in both 1963 and 1929, and the source and basis of its classification in 1963.⁹

Tables 1 and 2 provide a summary of the type of control, by number of corporations and by assets in 1963 and 1929, for the 200 corporations as a whole and for each of the three major industrial groups (industrials, public utilities, and transportation companies). A significant finding of this study is that management control¹⁰ has substantially increased among the 200 largest nonfinancial corporations since 1929. As Table 1 illustrates, 44 per cent of the 200 largest nonfinancial corporations in 1929 and 58 per cent of their assets were management-controlled. In 1963, however, 84.5 per cent of the "200 largest" of that year and 85 per cent of their assets were so controlled. Management control increased substantially within each of the three industrial groups and became the overwhelmingly predominant type of control within each group.

As shown in Table 1, private ownership had *completely disappeared* among the 200 largest nonfinancial corporations by 1963. Of the 12 privately owned firms on the 1929 list, six had dropped out of the "200 largest" by 1963. Of the remainder, one (A & P) was majority-controlled, four (Alcoa, Ford, Gulf Oil, and National Steel) were minority-controlled, and one (Jones & Laughlin) was apparently management-controlled. Only five companies (A & P, Duke Power Co., Kaiser Industries, Sun Oil, and TWA) were found to be majority-controlled in 1963, and in the case of TWA actual control was, at least temporarily, in the hands of trustees.

* Following the Berle and Means definitions, the author classified Tidewater Oil, Shell Oil, and the Coca-Cola Company as ultimately controlled by pyramiding because of their peculiar organizational structures, even though the evidence suggests that Tidewater and Shell are effectively majority-controlled and Coca-Cola effectively management-controlled. The Berle and Means definitions were followed exactly in order to keep the two studies as comparable as possible. Similarly, although Trans World Airlines is classified as majority-controlled, an equally convincing argument might be made for classifying it as controlled by a legal device, since Howard Hughes's 78 per cent stock interest (through the Hughes Tool Company) in TWA was, at least temporarily, being held in trust by a group of insurance companies and banks in 1963. Hughes's stock was sold to the general public in May, 1966. The TWA management was reported to be "anxious that no one should gain effective control—which might be done with as little as 10 per cent of the stock" [19, p. 145].

⁹ The principal sources used in determining type of corporate control were the definitive proxy statements filed with the SEC by all of the 200 corporations, the annual reports filed with the Interstate Commerce Commission by each railroad, and the annual reports filed with the Federal Power Commission by the utilities which it regulates. A more complete description of these sources and references to other sources used can be found in the appendix.

¹⁰ "Management control" without qualification should be understood to mean *ultimate* control by management. The same applies, *mutatis mutandis*, to the other types of corporate control.

* Includes corporations jointly controlled by two or more minority interests or jointly controlled by a minority interest and management.
Source: Berle and Means, *The Modern Corporation and Private Property* [4, p. 116].

Only 18 firms were found to be controlled by minority stockholders in 1963, roughly a third of the 46½ firms which Berle and Means classified as minority-controlled in 1929. Control through legal devices decreased even more sharply—from 41 in 1929 to 8 in 1963. On the other hand, the number of management-controlled firms almost doubled, from 88½ in 1929 to 169 in 1963.

Five companies on the 1963 list which are classified as management-controlled appear to be controlled, or at least very strongly influenced, by a single family within their management. Yet these families owned only a very small fraction of the outstanding voting stock. The five companies and their controlling families are: IBM (Watson), Inland Steel (Block), Weyerhaeuser (Weyerhaeuser), Federated Department Stores (Lazarus), and J. P. Stevens (Stevens). Federated Department Stores is the best illustration of this. In 1963 its chairman of the board, its president, and five of its 19 directors were members of the Lazarus family, even though the combined stock interest of the entire family was only 1.32 per cent. Since the present basis of control by these families appears to be their strategic position in management and the traditional identification of the corporation with the family rather than any appreciable amount of stock ownership, these companies are classified as management-controlled.

Management control was distributed rather evenly among the three industrial groups in 1963. Its highest incidence was among the utilities where it accounted for all but one of the 59 firms. Yet the public utilities had the lowest incidence of management-controlled firms in 1929 (38 per cent). This drastic change can be explained by the "death sentence" provision of the Public Utility Holding Company Act of 1935, which proscribes pyramiding beyond the second degree among public utility holding companies. Management control was the predominant type of control for the industrials and the transportation companies as well accounting for 78 per cent of the former and 83 per cent of the latter.

A significant difference between 1963 and 1929 is that the proportion of the 200 largest nonfinancial corporations that were management-controlled in the later year was about the same as the proportion of assets so controlled, while in 1929 the proportion of assets that were management-controlled was a good deal larger than the proportion of companies so controlled. This indicates that management control, which was concentrated among the larger firms on the 1929 list, has since reached down to relatively smaller (though absolutely larger) firms than it touched in 1929 and has become rather evenly distributed among the "200 largest." This contrast is illustrated by Table 3, which divides the "200 largest" of each year by rank into five groups of 40 firms each and lists the number of management-controlled firms in each group.

TABLE 3—"200 LARGEST" DIVIDED BY RANK INTO 5 GROUPS AND NUMBER OF MANAGEMENT-CONTROLLED FIRMS IN EACH GROUP

Firms Ranking	Number of Management-Controlled Firms	
	1963	1929
1 through 40	34	27
41 through 80	33	21
81 through 120	32	15½
121 through 160	37	15½
161 through 200	33	9½
Total	169	88½

Source: Appendix (see footnote 3)

This evidence suggests that a firm may reach a size so great that, with a few exceptions, its control is beyond the financial means of any individual or group. This point appears to have been reached only by the larger firms on the 1929 list, but by all of the firms on the 1963 list. The smallest corporation among the top 200 in 1963 had assets of 423 million current dollars or, deflating by the GNP deflator, 204 million 1929 dollars. A corporation of this size would have ranked 111th on the Berle and Means list. Of the 110 firms which would have ranked ahead of it, 55 per cent were management-controlled, compared with only 31 per cent of the remaining 90 firms. Moreover, many of the remaining 45 per cent of the top 110 firms in 1929 were either public utilities controlled by a kind of pyramiding which is now illegal or industrial firms still owned and controlled by their founder.

The present study may classify some firms incorrectly because of the limited information available to outsiders about the control of the 200 largest nonfinancial corporations. Generally, such errors would involve failure to locate an existing center of ownership (especially minority) control, so that the company is mistakenly classified as management-controlled. This would result, of course, in our overstating the extent of management control in 1963. Berle and Means, however, would seem to be in greater danger of overstating the extent of management control because of the less authoritative and less systematic sources of data upon which they had to rely and because of the larger minimum stockholding which they required as sufficient evidence of minority control. It follows that, even though the findings of the present study may overstate somewhat the *extent* of management control in 1963, they are also likely to understate the *change* in the extent of management control from 1929 to 1963 when compared with the findings of the Berle and Means study.

In summary, it would appear that Berle and Means in 1929 were observing a "managerial revolution" in process. Now, 30 years later,

that revolution seems close to complete, at least within the range of the 200 largest nonfinancial corporations.

THE GAIN FROM INTERNATIONAL TRADE AND INVESTMENT: A NEO-HECKSCHER-OHLIN APPROACH

By MURRAY C. KEMP*

1. That it may be to a single country's advantage to depress the volume of its foreign trade below the free trade level was known to Torrens, J. S. Mill, and Sidgwick;¹ and the more precise notion of an optimal degree of trade restriction (by means of an optimal tariff on imports or exports) goes back at least to Edgeworth and Bickerdike.² Rather later, it was recognized that a country may also gain by curbing its net international borrowing or lending,³ and that there may exist an optimal degree of restriction (by means of an optimal tax on foreign interest and profit receipts or payments).⁴

2. In this earlier literature, the gain from trade and the gain from international investment were implicitly assumed to be mutually independent and separately calculable. In conformity with this assumption, the calculation of the optimal degree of trade restriction and of the optimal curb on investment were treated as unrelated problems.

It is clear, however, that by changing the conditions of supply and the level of net income, both in the lending and in the borrowing country, international investment also may modify both the gain from trade and

* The author is research professor of economics in the University of New South Wales. He gratefully acknowledges the sustained assistance of Professor Henry Y. Wan, Jr., and of Professor Ronald Jones, especially with the more delicate arguments of Section II. He hopes that the results of Professor Jones's own investigations will soon be published. The author acknowledges also the useful comments of Professors Takashi Negishi and John Chipman on the penultimate draft.

¹ Torrens [36, pp. 281-82] and [37, Postscript to Letter IX, especially pp. 329-38]; Mill [19, pp. 21 ff.] and [20, Book V, Ch. 4, Sec. 6]; Sidgwick [32, pp. 493 ff.].

The notion that a tariff may turn the terms of trade in favor of the tariff-imposing country has a confusing and little-known early history. The principle was clearly stated by Torrens in 1824, in his *Essay on the Production of Wealth*, though the scope of the principle was unnecessarily restricted to circumstances in which the tariff-imposing country has "a natural monopoly, either partial or complete." The principle was reasserted by Torrens in an 1832 parliamentary speech (for details, see Robbins [23, pp. 192-94]) and, for the special case in which all import demands are of unit elasticity, was elaborated with great precision in *The Budget* of 1844 (the important Postscript to Letter IX was written in 1843). In order of writing, though not of publication, Torrens' 1844 exposition was preceded by that of J. S. Mill. In the preface to *Essays on Some Unsettled Questions of Political Economy* (1844) Mill mentions that they were written in 1829-30 and were being published in response to Torrens' *The Budget*.

³ Keynes [14] [16]; Iversen [8]; Cairncross [5]; Singer [34]; Nurkse [22]; Schonfield [30]. See also, however, Smith [35, Book II, Ch. 5].

⁴ MacDougall [18]; Rowan and Pearce [24].

the optimal degree of trade restriction. On the other hand, the restriction of trade changes the terms of trade and the relative profitabilities of investment at home and abroad; it therefore may affect the optimal degree of restriction of international investment. "Tariff factories" provide a simple and familiar example; the imposition of a tariff gives rise to an inflow of capital to finance the construction of branch plants behind the tariff wall; as a result, the terms-of-trade effect of the tariff is weakened, perhaps reversed. To treat trade and investment policies as separable and independent can be justified therefore only in a rough first approximation.

3. It is my purpose to formulate the problem of gain in a manner which will make clear the elements of interdependence, and to derive expressions for the optimal tariff and optimal tax.

In two earlier papers⁵ this has been attempted for the simple case in which each country produces a single commodity. In the present paper I shall instead work with a two-countries, two-commodities, two-factors model which is distinguished from the familiar Heckscher-Ohlin model, however, in that technology is allowed to differ between countries. The two factors recognized are labor and capital, the latter assumed to be homogeneous, perfectly durable, and smoothly substitutable for labor.⁶ Both factors are assumed to be in fixed supply: that is, the population of each country is stationary, and in each country net saving is zero. It is assumed that markets are perfectly competitive, all participants being well informed about world trading and investing opportunities. In particular, both factor markets are perfectly competitive, so that full employment is always assured, whatever commercial and fiscal policies are adopted. In keeping with the assumption of perfect competition, returns to scale are assumed to be constant. Finally, no account is taken of the possibility that one country may retaliate against the tariffs and taxes imposed by the other.

It will emerge that when account is taken of the elements of interdependence already referred to, either the optimal tariff or the optimal tax on foreign earnings, or both, may be negative.

I. Geometric Statement of the Problem

4. Putting aside net new borrowing, grants, indemnities, and remittances, every country is subject to a budget constraint of the form

$$\begin{aligned} & (\text{Quantity of Exports}) \text{ minus } (\text{Quantity of Imports}) \times (\text{Terms of Trade}) \\ & \quad \text{minus } (\text{Net International Indebtedness}) \times \\ & \quad \quad (\text{Average Earnings on Debt}) \\ & = 0 \end{aligned}$$

⁵ Kemp [10] [11]; also [12, Chs. 13 and 14].

⁶ Whatever its shortcomings in more general contexts, this assumption seems appropriate when stationary equilibria only are being considered. Cf. Samuelson [26].

FIGURE 1. GENERALIZED OFFER CURVE

The desired imports and exports of a country depend both on the terms of trade and on its net indebtedness. Suppose the latter is given. Then for each hypothetical value of the terms of trade we can plot desired imports and exports. By varying the terms of trade we can trace a locus of import-export combinations, each of which represents a potential international equilibrium. (Cf. Figure 1.) This locus is a straightforward generalization of the familiar foreign trade offer curve. Note, however, that only when net indebtedness is zero does the curve pass through the origin and that, except in that special case, it is not possible to read off the terms of trade corresponding to a particular point on the locus by simply connecting that point by a straight line to the origin—the capital

item in our equation complicates things. Note also that an equilibrium is possible in which the debtor country imports neither commodity; such an equilibrium would be located in the fourth quadrant of Figure 1.

Now take the foreign country's offer curve thus defined and slide it round the home country's production-possibilities curve in the manner made familiar by Baldwin [1] and Samuelson [27]. In this way is generated an envelope—the home country's consumption-possibilities curve (cc' in Figure 2). Throughout this exercise, however, the net indebtedness of each of the two countries has been held constant. Suppose now that the home country invests a little more or less in the foreign country and that this is accomplished by shipping equipment from one country to the other. Evidently both the home country's production frontier and the foreign country's (generalized) offer curve will shift, and there will emerge a new envelope. Consider the envelope of all such envelopes (CC' in Figure 2). This truly describes the consumption possibilities facing the home country.

The problem is to find that combination of import duty (or subsidy)

FIGURE 2. CONSUMPTION POSSIBILITIES CURVE

and income tax (or subsidy) which will move the home country to the favored point on its generalized consumption-possibilities curve.

II. *Solution of the Problem: Incomplete Foreign Specialization*

5. Until further notice it will be assumed that, if it is a net creditor, the home or policy-making country either exports the second commodity or exports nothing; and that, if it is a net debtor, the home country exports the second commodity or exports both commodities. The second commodity is, in this sense, the "natural" export of the home country.

For the time being it will be assumed also that each country produces something of both commodities.

Let X_i stand for the home output of the i th commodity and D_i for the home consumption of the i th commodity. $E_i (\equiv D_i - X_i)$ is then the home excess (or import) demand for the i th commodity. Let p stand for the price of the second commodity in terms of the first, r_1 for the return on one unit of capital (the marginal product of capital in terms of the first commodity), and K for the amount of capital invested abroad by the home country. (If K is negative, it stands for the amount of capital invested in the home country by the foreign country.) Asterisks relate the variables to the foreign country. Thus D_i^* stands for the foreign country's demand for the i th commodity and p^* for the world terms of trade. Finally, U is a concave Scitovsky⁷ index of the home country's welfare, a function of the aggregate amounts consumed by the home country of each of the two commodities, and of nothing else:

$$U = U(D_1; D_2) = U(X_1 + E_1; X_2 + E_2).$$

The foreign country, however, is subject to the budget constraint

$$(1) \quad E_1^* + p^* E_2^* + r_1^* K = 0;$$

moreover, in market equilibrium

$$E_i + E_i^* = 0 \quad i = 1, 2.$$

Hence the index may be written as

$$U(X_1 + p^* E_2^* + r_1^* K; X_2 - E_2^*).$$

Now foreign excess demand depends on the world terms of trade, on real income, and on the amount of capital invested abroad by the home country. However, real income is itself related to the terms of trade and to the level of net international indebtedness; hence we may simply write $E_2^* = E_2^*(p^*, K)$. We note also that, since the foreign country is assumed to be incompletely specialized, r_1^* depends on p^* , but not on

⁷ Scitovsky [31]. See also Samuelson [28].

K .⁸ We therefore may write $r_1^* = r_1^*(p^*)$, with $\partial r_1^* / \partial p^* \gtrless 0$ if, respectively, the second commodity is relatively capital-intensive, the two commodities are equally capital-intensive, or the first commodity is relatively capital-intensive. Finally, we note that the home output of the second commodity depends on the output of the first commodity and on the amount of capital invested abroad; that is, $X_2 = \varphi(X_1, K)$. [$\partial \varphi / \partial X_1$ is the slope of the production possibilities curve; $-\partial \varphi / \partial K$ is the marginal productivity of capital in terms of the second commodity, r_1/p .] It follows from all this that the welfare index can be written as a function of the three parameters X_1 , p^* , and K :

$$U[X_1 + p^* E_2^*(p^*, K) + r_1^*(p^*)K; \varphi(X_1, K) - E_2^*(p^*, K)].$$

Each of the three parameters can be varied as an act of policy. The problem is to find those values of X_1 , p^* , and K which maximize U .

It is worth noting, perhaps, that in this formulation of the problem the proceeds of the tariff and income tax are not explicitly recognized. This does not mean, of course, that matters of public finance are overlooked. The disposition of revenue is implicit in the selection of a social welfare function.

6. The first-order conditions of an interior maximum⁹ may be written:¹⁰

$$(2a) \quad U_2/U_1 = -1 / \frac{\partial \varphi}{\partial X_1}$$

$$(2b) \quad U_2/U_1 = \frac{p^*}{\eta_2^*} \left(1 + \eta_2^* + \frac{K}{E_2^*} \cdot \frac{\partial X_2^*}{\partial K} \right)$$

$$(2c) \quad U_2/U_1 = p^* \left(\frac{\partial X_2^*}{\partial K} - \frac{r_1^*}{p^*} \right) / \left(\frac{\partial X_2^*}{\partial K} - \frac{r_1}{p} \right)$$

where $U_i = \partial U / \partial D_i$, $\eta_2^* = (p^*/E_2^*)(\partial E_2^* / \partial p^*)$ is the total price elasticity of foreign import demand, and $\partial X_2^* / \partial K$ is the rate at which the foreign output of the second commodity responds to a unit change in the capital endowment, given the price ratio but assuming equilibrating adjustments in both industries.

⁸ With constant-returns technology, a given price ratio, and incomplete specialization, changes in the factor endowment give rise to changes in outputs but not to changes in factor proportions and (therefore) not to changes in marginal products.

⁹ Those boundary cases in which the home country is completely specialized or in which K lies at one of the upper and lower limits determined by the initial endowments will be considered in paragraph 12.

¹⁰ In writing equation (2b) use has been made of the fact that $\partial X_1 / \partial K = dr_1^* / dp^*$. This remarkable equality is proved in the Appendix. In writing equation (2c) use has been made of the fact that, given p^* , changes in K have no effect on net foreign real income and therefore no effect on foreign demand. Changes in K therefore affect $E_1^* (= D_1^* - X_2^*)$ solely through X_2^* : $\partial E_1^* / \partial K = -\partial X_2^* / \partial K$. Use has been made also of the relation: $-\partial \varphi / \partial K = r_1/p$.

7. The first of these three conditions states simply that the marginal social rate of substitution between the two commodities must equal the slope of the production frontier. This condition will be met under competitive conditions, when both are equal to the home price ratio.

8. The second condition may be interpreted as defining the optimal rate of duty. As we have just noted, $U_2/U_1 = p$; also, $p = p^*/(1 + \tau_1)$, where τ_1 is the *ad valorem* rate of import (or export¹¹) duty. The second condition may be written, therefore, as

$$1/(1 + \tau_1) = (1 + \eta_2^* + \epsilon_2^*)/\eta_2^*$$

where $\epsilon_2^* \equiv (K/E_2^*)(\partial X_2^*/\partial K)$ is the foreign elasticity of import production with respect to borrowed capital. It follows that the optimal rate of duty is

$$(3) \quad \tau_1 = - (1 + \epsilon_2^*)/(1 + \eta_2^* + \epsilon_2^*).$$

Now $\partial X_2^*/\partial K$, and therefore ϵ_2^* , may be of either sign: if the second commodity is relatively capital-intensive abroad, $\partial X_2^*/\partial K$ is positive; if the second commodity is relatively labor-intensive, $\partial X_2^*/\partial K$ is negative.¹² It follows that the optimal tariff may be of either sign, or zero.

Of special interest is the zero-indebtedness case, in which $K=0$. For then $\epsilon_2^*=0$ and the optimal rate of duty takes its familiar value:

$$(3') \quad \tau_1 = - 1/(1 + \eta_2^*).$$

It is not surprising perhaps that free trade is optimal if the foreign import demand is perfectly elastic ($\eta_2^* = \infty$) or, when the home country is a net creditor and imports *both* commodities, if the foreign supply of the second commodity is perfectly elastic ($\eta_2^* = +\infty$).

9. The interpretation of the third condition, contained in eq. (2c), is a little more intricate. Suppose that $K > 0$, that is, that the home country is a net creditor. Earnings per unit of capital, expressed in terms of the first commodity, are r_1^* . Suppose further that foreign earnings are subjected to a special income tax at a rate of $100t_1$ per cent. In competitive equilibrium the rate of return on capital will be the same in both countries; that is,¹³

¹¹ If, in the optimum, each country is an exporter, the tariff can be applied indifferently to the home country's imports of the first commodity or to its exports of the second commodity; the assignment of subscripts to τ is of no consequence. If, however, the home country is a net debtor and imports neither commodity, τ_1 must be interpreted as an *export* duty (levied on the *second* commodity). If, at the other extreme, the home country is a net creditor and exports neither commodity, the only possible interpretation of τ_1 is as an import duty (levied on the *first* commodity).

¹² Rybczynski [25].

¹³ It is assumed here and later that no duty is levied on repatriated dividends. In the contrary case, considered in my earlier articles [10] [12], $r_1 = r_1^*(1-t)/(1+\tau)$. The difficulty with the alternative assumption is that conclusions based on it do not carry over to a monetary economy.

$$(4) \quad r_1 = r_1^*(1 - t_1).$$

From equations (2b), (2c), and (3), on the other hand,

$$(5) \quad r_1 = r_1^*[1 + \epsilon_2^*(1 + \epsilon_2^*)/\mu_2\eta_2^*]$$

where $\mu_2 \equiv r_1^*K/p^*E_2^*$ is the ratio of the earnings on capital invested abroad to the value of exports. It follows from equations (4) and (5) that the optimal rate of tax on foreign earnings is

$$(6) \quad t_1 = -\epsilon_2^*(1 + \epsilon_2^*)/\mu_2\eta_2^*.$$

If $K < 0$, that is, the home country is a net debtor, it is the earnings on *foreign* capital which must be taxed. In competitive equilibrium

$$(7) \quad r_1(1 - t_1^*) = r_1^*$$

where t_1^* is the rate of tax. It follows from equations (5) and (7) that the optimal rate of tax is

$$(8) \quad t_1^* = \epsilon_2^*(1 + \epsilon_2^*)/[\mu_2\eta_2^* + \epsilon_2^*(1 + \epsilon_2^*)].$$

The tax rates t_1 and t_1^* are the counterparts, on capital account, of the more familiar optimal tariff. Like τ_1 , they may be of either sign. Note that when $|\eta_2^*| = \infty$, so that free trade is optimal, it also is optimal to refrain from tinkering with the international movement of capital. When $K = 0$, so that $\mu_2 = \epsilon_2^* = 0$, the optimal tax rates are, as one might have expected, indeterminate.

10. Inherent in equations (3), (6), and (8) is a quite confusing variety of possibilities. These are displayed in Figures 3a and 3b. Figure 3a covers the case in which the home country is a net creditor and Figure 3b describes the possibilities when the home country is a net debtor. (Note, however, that Figure 3a does double duty: when E_2^* is negative all t_1 -signs are reversed.) Depending on the values assumed by η_2^* and ϵ_2^* , it seems that any sign combination of rate of duty and tax rate is possible, that in particular both may be negative. But not all of these possibilities are plausible; indeed some regions may be ruled out altogether. This will now be shown.

First the elasticity of foreign import demand is decomposed into its pure substitution and income components. Thus

$$\begin{aligned} \eta_2^* &= \frac{p^*}{E_2^*} \cdot \frac{\partial E_2^*}{\partial p^*} \\ (9) \quad &= \frac{p^*}{E_2^*} \left\{ \frac{\partial D_2^*}{\partial p^*} \Big|_{v_1^* \text{ const.}} + \frac{m_2^*}{p^*} \cdot \frac{\partial y_1^*}{\partial p^*} - \frac{\partial X_2^*}{\partial p^*} \right\} \\ &= \bar{\eta}_2^* + \frac{m_2^*}{E_2^*} \cdot \frac{\partial y_1^*}{\partial p^*} \end{aligned}$$

FIGURE 3a. SIGN COMBINATION OF τ_1 AND ϵ_1

where

$$\bar{\eta}_2^* \equiv \frac{p^*}{E_2^*} \left\{ \frac{\partial D_2^*}{\partial p^*} \bigg|_{y_1 \text{ const.}}^* - \frac{\partial X_2^*}{\partial p^*} \right\}$$

is the pure elasticity of substitution, $m_2^* \equiv p^*(\partial D_2^*/\partial y_1^*)$ is the foreign marginal propensity to consume the second commodity, and y_1^* is the real income of the foreign country (that is, the cost, in terms of the first commodity, of the initial quantities consumed). Now

$$\begin{aligned}
 (10) \quad \frac{\partial y_1^*}{\partial p^*} &= \frac{\partial D_1^*}{\partial p^*} + p^* \frac{\partial D_2^*}{\partial p^*} \quad \text{by definition} \\
 &= -E_2^*(1 + \epsilon_2^*)
 \end{aligned}$$

from the budget restraint (1) and the duality relation of the Appendix.

Hence, substituting in equation (9),

$$(11) \quad \eta_2^* = \bar{\eta}_2^* - m_2^*(1 + \epsilon_2^*).$$

Adding $(1 + \epsilon_2^*)$ to both sides we have also

$$(12) \quad 1 + \eta_2^* + \epsilon_2^* = \bar{\eta}_2^* + m_1^*(1 + \epsilon_2^*).$$

Since $\bar{\eta}_2^*$ is the sum of the two pure substitution elasticities, of demand and production, it must be negative when E_2^* is positive and positive

FIGURE 3b. SIGN COMBINATIONS OF τ_1 AND ϵ_1^*

when E_2^* is negative. It then follows, from equation (11), (a) that when E_2^* is positive, positive η_2^* requires negative $(1+\epsilon_2^*)$ and therefore, from equation (12), negative $(1+\eta_2^*+\epsilon_2^*)$, and (b) that when E_2^* is negative, negative η_2^* requires positive $(1+\epsilon_2^*)$ and therefore, from equation (12), positive $(1+\eta_2^*+\epsilon_2^*)$:

$$(13a) \quad \text{if } E_2^* > 0 \quad \text{then} \quad \eta_2^* > 0 \quad \text{implies} \quad 1 + \eta_2^* + \epsilon_2^* < 0$$

$$(13b) \quad \text{if } E_2^* < 0 \quad \text{then} \quad \eta_2^* < 0 \quad \text{implies} \quad 1 + \eta_2^* + \epsilon_2^* > 0.$$

Further restrictions may be inferred from the requirements (i) that import and export subsidies must fall short of 100 per cent (if they did not, competition would force the price of the subsidized commodity to zero or below) and (ii) that the rate of income tax must fall short of 100 per cent. Thus, from equation (3),¹⁴

$$(14) \quad -1 < \tau_1 = -(1 + \epsilon_2^*)/(1 + \eta_2^* + \epsilon_2^*)$$

and, from equations (6) and (8), respectively,

$$(15a) \quad 1 > t_1 = -\epsilon_2^*(1 + \epsilon_2^*)/\mu_2\eta_2^*$$

and

$$(15b) \quad 1 > t_1^* = \epsilon_2^*(1 + \epsilon_2^*)/[\mu_2\eta_2^* + \epsilon_2^*(1 + \epsilon_2^*)].$$

It is possible that further restrictions on η_2^* and ϵ_2^* can be teased out of the higher order conditions for a maximum, but I have been unable to do so.

When all restrictions are taken into account we are left with the possibilities displayed in Figures 4a–4c. Figure 4a illustrates the case in which, in the optimum, the home country is a net creditor and continues to export the second commodity (so that $K > 0$, $\mu_2 > 0$); Figure 4b illustrates the case in which the home country is a net creditor but imports both commodities (so that $K > 0$, $\mu_2 < -1$, and the optimum occurs in the fourth quadrant of Figure 1); Figure 4c illustrates the case in which, in the optimum, the home country is a net debtor and exports the second commodity only (so that $K < 0$, $-1 < \mu_2 < 0$); and Figure 4d illustrates the remaining case in which the home country is a net debtor and exports both commodities (so that $K < 0$, $\mu_2 < -1$, and the optimum occurs in the second quadrant of Figure 1).

The most striking feature of Figures 4a and 4b, which between them cover the case in which the home country is a net creditor, is the possibility that the optimal tariff and/or the optimal tax may be zero or negative. Both may be zero, so that free trade in goods and unrestricted

¹⁴ Alternatively, inequality (14) may be obtained by noting that the concavity of U rules out negatively sloped sections of the foreign country's offer curve (cf. Figure 1). The detailed proof is omitted.

FIGURE 4a. $K > 0$, $\mu_3 > 0$

capital mobility are optimal; and, if the home (or creditor) country imports both commodities, both may be negative. As Figures 4c and 4d make clear, however, there is not in the case of net home indebtedness quite the same richness of possibilities. In that case the optimal tariff or the optimal tax may be negative; but it is not possible for both to be negative, even when the home (or debtor) country exports both commodities.

It is noteworthy also that in none of the four cases distinguished is the elasticity of foreign import demand restricted to values algebraically less than minus one. This conclusion contrasts with a standard result of the

FIGURE 4b. $K > 0$, $\mu_2 < -1$

theory of optimal tariffs and reflects the fact that a variation of the terms of trade affects not only foreign import demand but also the rate of return on foreign investment. Thus if sufficient additional investment income is generated thereby, it will pay the home country to push the terms of trade below the point of zero marginal export income.

That an optimal tariff or tax may be negative is paradoxical. To help dispel the paradox, consider the following line of thought, valid for the case of capital export. When it parts with a unit of capital, the home country sacrifices production valued in terms of the first commodity at

r_1 . This loss must be weighed against the additional goods made available by the foreign country after its economy has adjusted to the increment of capital. The net addition to the flow of goods available to the home country is, in terms of the first commodity, $-[(\partial E_1^*/\partial K) + p(\partial E_2^*/\partial K) + r_1]$ or, since net foreign real income, and therefore foreign demand, is unaffected by the capital movement, $(\partial X_1^*/\partial K) + p(\partial X_2^*/\partial K) - r_1$. Now the rate of return abroad is $r_1^* = (\partial X_1^*/\partial K) + p^*(\partial X_2^*/\partial K)$. Hence the net social return on the marginal investment is $[r_1^* - r_1 + (p - p^*)(\partial X_2^*/\partial K)]$. In an optimum this expression must equal zero. It follows that the optimal tax, t_1 , is positive if the home country places a lower valuation on the commodity the foreign production of which has increased than does the foreign country. This occurs if the home country's export good is capital-intensive abroad (so that $\partial X_2^*/\partial K > 0$) and a tariff is levied (so that $p < p^*$): Region I' of Figure 4a and Region V' of Figure 4b; or if the export good is labor-intensive

 FIGURE 4c. $K < 0$, $-1 < \mu_1 < 0$

tion of which has increased than does the foreign country. This occurs if the home country's export good is labor-intensive abroad and a tariff is levied (so that $p < p^*$): Region I' of Figures 4c and 4d; or if the home country's export good is capital-intensive abroad and an export subsidy is paid: Region III' of Figures 4c and 4d. Obversely, a subsidy on foreign earnings is optimal if the home country places a lower valuation on the commodity the foreign production of which has decreased than does the foreign country. This occurs if the home country's export good is capital-intensive abroad and a tariff is levied: Region II' of Figures 4c and 4d.

11. If both the optimal import duty and the optimal income tax are negative, net tax revenue also is negative. However, it is not in this case only that the operation of an optimal system of tariffs and taxes will leave the Treasury out of pocket. Whether the home country is on balance a creditor or on balance a debtor, net revenue is

$$(16) \quad p^* E_2^* (1 + \epsilon_2^*) (1 + \epsilon_2^* + \mu_2) / \eta_2^*.$$

From Figures 4a–4d it is clear that, in an optimum, $-p^* E_2^* / \eta_2^*$ is positive. Hence, if ϵ_2^* lies between -1 and $-(1 + \mu_2)$, as it does in Region VI' of Figure 4b, expression (16) is negative; otherwise, it is positive. When the home country is a net creditor and continues to export (Figure 4a), net revenue is necessarily positive if $\epsilon_2^* > 0$, that is, if the second commodity is relatively capital-intensive abroad; it is a necessary, but not sufficient, condition of negative net revenue that the second commodity be relatively labor-intensive abroad. When the home country is a net debtor and continues to import (Figure 4c), net revenue is necessarily positive if $\epsilon_2^* > 0$, that is, if the second commodity is relatively labor-intensive abroad; it is a necessary, but not sufficient, condition of negative net revenue that the second commodity be relatively *capital*-intensive abroad. In other cases (illustrated by Figures 4b and 4d) no statements of comparable simplicity seem possible.

12. So far we have confined our attention to interior optima. Specifically, we have put aside both the possibility that it is optimal for the home country to specialize completely and the possibility that the optimal K assumes one or other of the two extreme values determined by national capital endowments.

Fortunately our conclusions, with minor modifications, cover also the possibility of complete home specialization. For then $X_1 = 0$ and the welfare index becomes

$$U\{0 + p^* E_2^*(p^*, K) + r_1^*(p^*)K; \varphi(0, K) - E_2^*(p^*, K)\},$$

a function of two parameters only, p^* and K . The first-order conditions are identical with those contained in equations (2b) and (2c), hence the optimal tariff and tax are as set out in equations (3), (6), and (8). Equa-

tion (2a) no longer holds, and must be replaced by a suitable inequality.

Similarly, if the optimal K lies at its upper limit, set by the home country's capital endowment, equation (2c), and therefore equation (6) must be replaced by an inequality. Equation (6), for example, becomes

$$(6') \quad t_1 \geq -\epsilon_2^*(1 + \epsilon_2^*)/\mu_2\eta_2^*.$$

If, on the other hand, K lies at its lower limit, set by the foreign country's capital endowment, equation (8) becomes

$$(8') \quad t_1^* \geq \epsilon_2^*(1 + \epsilon_2^*)/[\mu_2\eta_2^* + \epsilon_2^*(1 + \epsilon_2^*)].$$

13. It has been assumed also that the home country exports the second commodity. The analysis of the alternative possibility is, however, symmetrical with that already provided. All results may be obtained by simply permuting the subscripts in equations (3), (6), and (8).

III. *Solution of the Problem: Complete Foreign Specialization*

14. The discussion of Sec. II was limited to the case of incomplete foreign specialization. The same general approach can be applied to the classical case in which the foreign country produces one commodity only. The cases differ, however, in two important respects. In the first place, the return on foreign investment, r_1^* , now depends on the level of net indebtedness, K , but not on the terms of trade, p^* ; specifically $\partial r_1^*/\partial p^* = \partial X_2^*/\partial K = \epsilon_2^* = 0$, and $\partial r_1^*/\partial K < 0$. Second, it is no longer true that net foreign real income is, for given terms of trade, invariant under changes in K . Thus, if the foreign country is completely specialized in the production of the first commodity, we have

$$\begin{aligned} \frac{\partial E_2^*}{\partial K} &= \frac{\partial D_2^*}{\partial K} = \frac{\partial D_2^*}{\partial I_1^*} \cdot \frac{\partial I_1^*}{\partial K} \\ &= \frac{m_2^*}{p^*} \left(-K \frac{\partial r_1^*}{\partial K} \right) \\ &= -\frac{m_2^*}{p^*} r_1^* \delta_1 \end{aligned}$$

where $\delta_1 \equiv (K/r_1^*)(\partial r_1^*/\partial K)$ is the elasticity of the foreign rate of return with respect to foreign investment, and I_1^* is the income of the foreign country in terms of the first commodity.

In view of these differences, equation (3) must be replaced by

$$(3') \quad \tau_1 = -1/(1 + \eta_2^*),$$

equation (2c) becomes

$$(2c') \quad U_2/U_1 = r_1^*(1 + \delta_1 m_1^*) / \left[\frac{r_1}{p} - \frac{m_2^* r_1^* \delta_1}{p^*} \right],$$

equation (5) is replaced by

$$(5') \quad r_1 = r_1^* \{ 1 + \delta_1 [m_1^* + m_2^* (1 + \eta_2^*) / \eta_2^*] \},$$

and equation (6) becomes

$$(6'') \quad t_1 = -\delta_1 [m_1^* + m_2^* (1 + \eta_2^*) / \eta_2^*].$$

Finally, (8) is replaced by

$$(8'') \quad l_1^* = \frac{\delta_1 [m_1^* + m_2^* (1 + \eta_2^*) / \eta_2^*]}{1 + \delta_1 [m_1^* + m_2^* (1 + \eta_2^*) / \eta_2^*]}.$$

Equations (6'') and (8'') may be reached also by a line of reasoning similar to that pursued on pp. 799-803.

15. It is easy to show that in the present case, with complete specialization abroad, both the optimal tariff and the optimal tax must be positive. That is, it never pays to subsidize imports or exports, nor does it pay to subsidize borrowing or lending. To see that the optimal tariff must be positive, note first that if the foreign country is completely specialized, equation (10) reduces to

$$\frac{\partial y_1^*}{\partial p^*} = -E_2^*,$$

and that (11) therefore reduces to

$$(17) \quad \eta_2^* = \bar{\eta}_2^* - m_2^* < 0;$$

equation (13), on the other hand, reduces to

$$(18) \quad -1 < \tau_1 = -1/(1 + \eta_2^*).$$

From equations (17) and (18) it follows that $\eta_2^* < -1$.

To see that the optimal tax must be positive one need only note that $(1 + \eta_2^*) / \eta_2^* = 1 / (1 + \tau_1) = p / p^* > 0$ and that $\delta_1 \geq 0$ as $K \leq 0$.

That both the optimal tariff and the optimal tax must be positive is of considerable intrinsic interest for, at least since Ricardo, the case of complete specialization has possessed a special fascination for trade theorists. But the result is also interesting for the light it throws on some of our earlier conclusions; in particular, it helps us to see why a negative tax may be optimal when the foreign country produces something of both commodities. If the foreign country is completely specialized there is a direct link between K and r_1^* . An increase in the amount lent abroad inevitably depresses the rate of return, hence it can never pay to subsidize foreign lending. When foreign specialization is incomplete, however,

the direct link is broken, and with that link goes the inevitability that the tax is positive. The several cases described towards the end of paragraph 7 become possible.

IV. *Brief Comments on the Results*

16. It has been shown how one may solve for the optimal K , p^* , and X_1 , and for the associated τ 's and t 's. It should be noted that the solutions depend on η_2^* , the elasticity of foreign import demand. Putting aside the special, constant-elasticity case, however, the value of η_2^* depends on the price at which it is calculated. That in turn depends on the choice of U -function. Thus, the optimal rates of duty and tax vary with the specification of U . That the optimal tariff is in this sense not unique is well known;¹⁵ we now see that the same is true of the optimal tax on foreign earnings.

17. Equations (3), (6), and (8) contain the term ϵ_2^* , based on $\partial X_2^*/\partial K$ both of which are unfamiliar. They are, however, easy to translate into parameters of production functions. This is done in the Appendix.

18. The discussion has run in terms of comparative stationary states. Under stationary conditions the optimal tariff and tax are themselves stationary. It should be possible, however, to generalize the analysis to accommodate steadily growing or declining resource endowments and steadily improving technologies. If the assumptions of the present paper are retained, the results are bound to be messy. If, however, the capital good is identified with one of the consumer goods—a characteristic simplification of modern growth theories—a fairly elegant analysis should be possible.¹⁶

19. It has been assumed that in its choice of tariff and tax rate the policy-making country is constrained only by considerations of demand and technology. One can imagine, however, a second-best situation in which the policy-making country is further constrained by, for example a commitment to free trade or to maximum rates of duty or by an international tax convention. The interesting questions then concern the extent to which a country can achieve its over-all commercial-investment objectives with only the commercial (or investment) lever to manipulate or, more generally, with constraints on the extent to which the levers can be manipulated. The analysis can be extended to cope with such questions, though it might prove convenient to rewrite the U -function in terms of the alternative parameters X_1 , τ_1 , and t_1 (or t_1^*).

20. There are in our model not two but three traded goods, two consumption goods and the services of capital, and the optimal tax can be considered as the optimal tariff on trade in capital services. It is well known that if there are three traded consumption goods, it may pay to

¹⁵ Cf. Scitovsky [31]; Graaff [7, pp. 136–37].

¹⁶ A first step in this direction has been taken by Professor Takashi Negishi in [21].

subsidize trade in one of them (Graaff [7]). It now appears that the result can be extended by allowing one of the traded goods to be intermediate. On the other hand, it appears that the possibility of negative net revenue carries over to the case in which all traded goods are consumer goods.

21. If more than two countries are recognized the analysis becomes much more complicated, for then the pursuit of an optimum may require discrimination among the home country's trading partners. Thus, the optimal rate of duty on any particular good will depend on the amount invested in the supplying country; and the optimal tax on earnings derived from a particular foreign country will depend on the amount of trade carried on with that country and on the ϵ_1^* values of that country.

22. Finally, the reader is reminded of the long list of assumptions contained in paragraph 3, in particular of the assumptions of full employment and perfect competition. He might try his hand at a Keynesian (or neo-Mercantilist) reworking of the paper, or he might ask himself how many of our conclusions would be helpful to an oil sheik in his negotiations with the larger oil companies.

APPENDIX

23. In deriving equation (2b) use was made of the dual relationship $dr_1^*/dp^* = \partial X_2^*/\partial K$. This appendix contains a proof of that equality. Actually, the relationship was stated and proved some years ago by Paul Samuelson [29, p. 10]. But the proof was barely sketched and is, in any case embedded in an especially difficult article. The following straightforward proof may therefore be of interest.

24. If the foreign country is completely specialized in the production of its export commodity, the proof is trivial. For then, $\partial X_2^*/\partial K = 0$ and, since $r_1^* = \partial X_1^*/\partial K$, $dr_1^*/dp^* = 0$. In what follows, it will be assumed that the foreign country produces something of both commodities.

25. Given constant returns to scale, the two foreign production relationships may be expressed as

$$(A1) \quad X_i^* = k_i f_i(\rho_i) \quad i = 1, 2$$

where X_i^* is the output of the i th commodity, k_i is the amount of capital employed in the i th industry, and ρ_i is the labor:capital ratio in the i th industry. In a competitive equilibrium the following marginal equalities hold:

$$(A2) \quad \begin{aligned} f'_1 - p^* f'_2 &= 0 \\ r_1^* &= (f_1 - \rho_1 f'_1) = p^* (f_2 - \rho_2 f'_2), \end{aligned}$$

[$f'_i \equiv df_i/d\rho_i$ is the marginal productivity of labor in the i th industry; and $(f_i - \rho_i f'_i)$ is the marginal productivity of capital in the i th industry]. Finally we have two "full employment" conditions.

$$(A3) \quad \begin{aligned} k_1 + k_2 &= K + \text{const.} \\ k_1\rho_1 + k_2\rho_2 &= \text{const.} \end{aligned}$$

Treating K and p^* as parameters, and differentiating the entire system (A 1-3) with respect to K , we obtain

$$\partial X_2^*/\partial K = -\rho_1 f_2/(\rho_2 - \rho_1) \quad Q.E.D.$$

26. By similar reasoning,

$$dr_2^*/d(1/p^*) = \partial X_1^*/\partial K$$

where r_2^* is the foreign marginal product of capital in terms of the second commodity.

PEAK-LOAD PRICING AND OPTIMAL CAPACITY UNDER INDIVISIBILITY CONSTRAINTS

By OLIVER E. WILLIAMSON*

The problem of peak-load pricing has been "solved" at least four times in the postwar literature (by Marcel Boiteux [1], Hendrik Houthakker [4], Peter Steiner [7], and Jack Hirshleifer [3]), and thus an additional treatment of this subject requires some justification.¹ Ours is threefold. First, the welfare motivation of these analyses has been generally lacking,² and it is therefore difficult to evaluate the results obtained. Second, the geometric techniques that have been provided are awkward and unconventional, require that costs be redefined for each change in the number of subperiods, and cannot easily be generalized to handle the case of unequal-duration-subperiod loads. We attempt to remedy each of these deficiencies and, in addition, extend the analysis of peak-load pricing by replacing the usual assumption of fully divisible plant by one in which investment opportunities are discrete. This latter may be of little practical importance,³ but it helps shed additional insights on the welfare attributes of the problem.

* The author is associate professor of economics at the University of Pennsylvania on leave as Special Economic Adviser to the Assistant Attorney General for Antitrust. The views expressed in this paper do not necessarily reflect those of the Department of Justice. Discussions with Jack Hirshleifer helped clarify some of the earlier work in the peak-load pricing area, and his comments on this paper are gratefully acknowledged. Research on this paper was supported by a grant to the author from the National Science Foundation and from the Lilly Foundation grant to the University of California, Los Angeles, for the study of the economics of property rights.

¹ The problem of peak-load pricing has also been treated recently by Arnold Harberger and N. Andreatta [2]. Their paper appears to be an application of the previous literature to the electricity-supply problems in India, with special attention to the question of optimal use of thermal and hydro capacity. Since they make no references to the earlier literature, their paper may represent still another "solution."

² Steiner sketches the welfare objective in a footnote [7, p. 587, n. 6] but fails to integrate the argument with the text beyond calling for a price-equal-marginal-cost result. Houthakker supplies a more comprehensive welfare motivation for his analysis, but he is concerned only with conditions that prevailed in Great Britain in the early 1950's. Since these conditions appear to be somewhat special, the applicability of the results is correspondingly circumscribed (which he explicitly points out [4, p. 1]). Our analysis, like those of Boiteux, Steiner, and Hirshleifer, is concerned with the general problem rather than with a particular set of time-place conditions. Our reference to "earlier treatments" in subsequent parts of this paper will therefore be restricted to these latter writers unless otherwise indicated.

³ Houthakker claims that indivisibilities are unimportant in Great Britain since they operate in a fully interconnected system [4, p. 9]. Regions where interconnections are less extensive and economic generating units represent a nontrivial fraction of market size are presumably ones where indivisibilities could be significant. One caveat is, however, essential:

The welfare motivation for the analysis is supplied in Section I. Optimal pricing and the optimal adjustment of capacity to changes in demand, given a single uniform class of demands but indivisible plant, are investigated in Section II. The principal part of the paper is Section III, where a perfectly general geometric technique for combining periodic loads, given that costs are linear and subperiod demands are independent, is provided. Once costs are correctly specified, we show that the problem of optimally adjusting capacity in a periodic-load situation can always be solved by use of our "effective demand for capacity" construction. Criteria for optimal pricing to peak and off-peak loads are also derived. As contrasted with the optimal capacity problem, optimal pricing to periodic demands is not a weighting problem but involves efficient use of existing capacity to service each demand class taken separately.

I. *The Social Welfare Function*

We simplify our analysis by assuming that all of the optimum conditions of production and exchange are satisfied elsewhere in the economy. This is a strong assumption and may vitiate the analysis in the minds of some. However, some such assumption is necessary if we are to avoid "second best" digressions, and implicitly this assumption underlies the analyses of Boiteux, Steiner, and Hirshleifer. We are therefore merely making explicit what has previously been implicit in the peak-load-pricing literature. Moreover, since this assumption supplies us with conditions which permit us to employ the theoretical apparatus of partial welfare economics *to derive benchmark relations* if nothing else, and as there is no well-specified alternative (the claim that our assumptions are not obviously satisfied needs to be articulated before it becomes useful), we will proceed on this basis.⁴

Social benefit will therefore be given by total revenue plus consumers' surplus, and social cost (treated as opportunity cost and assuming no technological externalities) will be separable into total pecuniary cost less intramarginal rent. Assuming that all factors are available to the enterprise in completely elastic supply, intramarginal rents will be zero and the net welfare gain is:

although the presence of indivisibilities implies lumpiness in certain inputs, the lumps cannot be so large as to produce changes in relative outputs and prices over the whole economy. If this were the case, our partial equilibrium approach would have to be replaced by a general equilibrium analysis.

⁴ That assumptions of this sort are enormously helpful in producing insights on complex economic questions is illustrated by the remarkably insightful treatment of the fishery regulation problem by Ralph Turvey [8]. The reason we believe he was able to get so far with the fishery problem is precisely because he was willing to make simplifying assumptions and thereby provide a fundamental welfare motivation for his analysis.

$$(1) \quad \begin{aligned} W &= SB - SC \\ &= TR + S - TC \end{aligned}$$

where W =net welfare gain, SB =social benefit, SC =social cost, TR =total revenue, S =consumers' surplus, and TC =total cost.

Differentiating this expression with respect to output, we obtain the necessary⁵ and sufficient conditions for a maximum the familiar relations:

$$(2) \quad \frac{dW}{dQ} = \frac{d}{dQ} (TR + S) - \frac{d}{dQ} (TC) = 0$$

whence $P - MC = 0$

$$(3) \quad \frac{d^2W}{dQ^2} = \frac{dP}{dQ} - \frac{d^2}{dQ^2} (TC) < 0.$$

Assuming that we have completely divisible plant, that capacity cost (defined more precisely in Section II) are β per unit per period, and that operating costs are b per unit per period, we have:

$$(4) \quad TC = (b + \beta)Q,$$

so that by (2) the optimal scale (for a given uniform class of demands) will be that value of Q for which $P = b + \beta$.

If the physical plant is taken as given and the only decision is one of pricing optimally within the capacity constraint (\bar{Q}), we have:

$$(5) \quad \begin{aligned} \max W &= (TR + S) - bQ \\ \text{s.t. } Q &\leq \bar{Q}. \end{aligned}$$

Setting this up as a Lagrangian

$$(6) \quad \max L(Q, \lambda) = (TR + S) - bQ - \lambda(Q - \bar{Q}),$$

⁵ That the derivative of the total revenue plus consumers' surplus term ($TR + S$) with respect to quantity is simply price can be seen from the fact that

$$TR + S = \int_0^Q P(Q') dQ', \text{ where } P(Q') \text{ is}$$

the demand curve. Differentiating this expression with respect to Q yields

$$\begin{aligned} \frac{d}{dQ} (TR + S) &= \frac{d}{dQ} \int_0^Q P(Q') dQ' \\ &= P(Q). \end{aligned}$$

As pointed out below, we treat $P(Q')$ as the uncompensated demand curve and thus consumers surplus is given by the Marshallian triangle. It is not necessary, however, to define consumers surplus in this way to show that the welfare gain is maximized by equating price to marginal cost. But clearly this specification leads to the $P = MC$ result, which is all that we require in order to support the argument in the text.

and differentiating partially with respect to Q and λ and equating to zero, we have:

$$(7) \quad P = b + \lambda$$

$$(8) \quad Q \leq \bar{Q}.$$

By the Kuhn-Tucker Theorem [5], if the constraint is not binding and equation (8) is satisfied as an inequality, λ is zero, and the optimal price is where output equates price to short-run marginal cost, namely b . When the capacity constraint is reached, however, the value of λ becomes positive, and the resulting price necessarily exceeds b . If $b + \lambda > b + \beta$ (and demand is expected to continue at this level), an expansion of plant is signaled, whereas if $b + \lambda < b + \beta$, plant should be retired.⁶

The above are the principal optimality rules for a system in which plant is fully divisible and a single uniform class of demands exists. We turn now to consider the effects of relaxing these two assumptions. First, however, two characteristics of our welfare function not explicitly stated above are noted: (1) benefits and costs are weighted equally "to whomsoever they may accrue," and thus society is indifferent to the income redistribution effects under this formulation; (2) the welfare function can be rearranged in a form more convenient for the subsequent exposition by expressing it as

$$(1') \quad W = S + (TR - TC)$$

where the first term is the consumers' surplus and the second term the producers' net revenue. For purposes of symmetry (although contrary to the standard usage, where the expression applies only to rents to intramarginal factors) we will refer to this net revenue term as "producers' surplus."

II. Uniform Load and Indivisible Plant

As already indicated, we distinguish between operating costs and capacity costs. Operating costs are mainly the energy costs of generation and transmission. Marginal operating costs (short-run marginal costs) are assumed to be constant, at a rate of b per unit per period, so long as output is less than capacity. When capacity is reached, however, marginal operating costs become effectively infinite. Thus a sharp kink develops at the existing capacity level.

Plant can be efficiently supplied only in integer multiples of output units of size E and cost Γ . The foregone alternative is an equivalent risk

⁶ If $b + \lambda > b + \beta$, clearly $\lambda > \beta$ and the shadow price of the constraint exceeds the cost of installing an additional unit of capacity. Hence plant expansion is indicated. Where $b + \lambda < b + \beta$, so that $\lambda < \beta$, plant should be retired rather than renewed until an equality between λ and β is restored.

annuity which pays an amount γ per period over the useful life of the plant. Average capacity costs per period of a fully utilized efficiency unit of size E are thus γ/E plus the average maintenance cost per period, the sum of which we will call β . Subject to these indivisibility conditions, constant returns to scale prevail and long-run marginal costs are given by $b + \beta$.

FIGURE 1

We assume that the enterprise is initially in a fully adjusted equilibrium position in which short-run marginal costs, long-run marginal costs, and price are all equal. This is shown in Figure 1 where the demand curve is D_1 and the output $Q_1^* = nE$, where n is a positive integer. Price in these circumstances will be $b + \beta$ so that total revenue equals total cost. Producers' surplus is therefore zero and the net gain, W , is

given by the consumers' surplus region UNG (assuming constant marginal utility of money over the relevant range).⁷

Assume now we have a once-for-all shift in demand to D_2 . Under what conditions does it become optimal to add a new capacity unit? Clearly if D_2 were to pass through K so that at a price of $b+\beta$ the quantity demanded would be Q_1^*+E , a new efficiency unit would be warranted. But what if D_2 passes through some intermediate position between N and K such as J ? Is there any justification for adding a new efficiency unit under these circumstances, and if so what price should be charged? Given our welfare function, the answer is clearly affirmative and the condition under which it becomes desirable is when the area $IJJN$ just exceeds the area JKL . With the new capacity unit in place, the appropriate price is given by the intersection of $SRMC_2$ with D_2 , namely P_2 .

To see that this is the condition under which the new efficiency unit should be added suppose that, with demand at the level D_2 , the area $IJJN$ is just equal to JKL and the enterprise continues to operate with Q_1^* units of capacity. A price of P_1 will be required to ration capacity output under these conditions. Thus producers' surplus (total revenue less total cost) will be given by $HING$ and consumers' surplus will be VIH . The welfare gain will be the sum, or $VING$. Should a new efficiency unit be added and price set at OF (where D_2 and $SRMC_2$ intersect), we find producers' surplus reduced in the amount $HING+GJLF+JKL$ while consumers' surplus increases by $HING+GJLF+IJN$. Thus the net gain is $IJJN-JKL$, which by assumption is zero. Hence, from a welfare point of view, one is presumably indifferent between remaining at Q_1^* and moving to Q_1^*+E . But whenever $IJJN > JKL$ the net welfare gain will be positive, in which case the new efficiency unit should be added and, for all positions intermediate between J and K , the enterprise will be operated at a loss.

Indeed we see that, in this system with indivisible plant, the fully adjusted long-run static equilibrium can be one in which either positive or negative net profits are realized despite (discontinuously) constant returns to scale. Only accidentally⁸ will the enterprise earn zero profits at the welfare maximum.

If the assumption that the shift from D_1 to D_2 is a once-for-all change is replaced by one in which D_2 is merely a transitory position in a system where demand is continuously increasing, does our criterion for installa-

⁷ This is another simplifying assumption, but one which, we suspect, is not likely to be seriously violated. See Alfred Marshall [6, pp. 132, 334-35, 842] for a similar view that the inaccuracy involved in employing this assumption is usually negligible. D. M. Winch has recently argued that, even where the marginal utility of money is not constant, the Marshallian triangle continues to be an accurate measure of what he refers to as "consumers' gain" so long as income distribution is a matter of indifference [9, pp. 395-407, 422].

⁸ This will occur with probability zero if demand is a random variable with continuous distribution function.

tion of the additional capacity require modification? In some superficial sense it might appear that these dynamic conditions would warrant installation prior to the time at which the static criterion is satisfied. It is obvious, however, that if the new capacity is added before the area $IJN \geq JKL$, the welfare gain is less in those periods when $IJN < JKL$ than it otherwise would be, and no type of discounting procedure that expresses future gains in terms of present values will alter this result. Thus the criterion for installation remains the same: add the new capacity when IJN first exceeds JKL , but not before.⁹

The introduction of uncertainty requires that the analysis be adapted accordingly. In circumstances such as these where we are prescribing optimal social policy and the risk of *system* ruin due to the failure of any particular *enterprise* is negligible, and where we are assuming that the mix of projects is suitably diversified so as to secure the advantages of pooling, special allowance for risk would appear unnecessary. Instead, simple conversion to expected values would seem appropriate so that the counterpart of our previous criterion is to add capacity whenever $E(IJN) \geq E(JKL)$, where $E(\cdot)$ denotes expectation.

III. Peak and Off-Peak Loads

The analysis of periodic loads requires that costs and demands be specified with more than ordinary care. Specifications that conveniently solve a special case (such as the principal case examined by Boiteux, Steiner, and Hirshleifer in which there are two loads, each of identical length) may be difficult or awkward to generalize. Even more serious, the "apparent" generalization may lead to error. We therefore take *the entire demand cycle* as the natural unit against which to express costs. Assuming that the "period" referred to in Sections I and II is the same length as an entire cycle (typically a day), the specification of costs used

⁹ If there is an installation lag, of course, it will be necessary to anticipate demands in order for capacity to be operative at the desired time. With a positive rate of interest, the capacity should be timed to come into operation after $IJN > JKL$. This correction is trivial, however, and also applies if there is an installation lag under once-for-all changes in demand.

If the assumption of continuously increasing demand is replaced by one of secularly increasing demand with cyclical variation about the trend, the criterion still remains largely intact. Thus, installation lags aside, installation never precedes but is always made subject to the condition that $IJN \geq JKL$. However, whereas this was the necessary and sufficient condition for adding capacity under our welfare criterion given the static or continuously increasing demand conditions, it is only a necessary condition when cyclical variation is present. Whether the installation should be made at the time that demand first satisfies this relation, or be deferred to the second or n th time that the inequality $IJN < JKL$ is reversed, depends on the phase and frequency of cyclical variation. More specifically, our objective is to time the installation so as to maximize the discounted value of net benefits, and this need not coincide with the first switch-over from $IJN < JKL$ to $IJN \geq JKL$. Thus if, for example, the first switch-over occurred at the very peak of a cycle, installation at the time of the switch-over would be quite without purpose for the downturn would set in immediately and the additional capacity would exceed optimal ($IJN < JKL$).

previously applies directly to our analysis of peak-load pricing. Thus under our formulation there is no difference between the conventional costing practices used in the analysis of uniform loads and those used to study the periodic-load problem, whereas this is not true in each of the papers referred to above. We therefore define short-run marginal costs as the operating costs of supplying the incremental unit of output (at levels of operation less than capacity) over an entire cycle, namely b per unit per cycle. Since incremental capacity costs continue at the rate of β per unit per cycle, long-run marginal costs are $b + \beta$ per unit per cycle.

In order for this specification of costs to be "appropriate" to the problem of peak-load pricing, it is also necessary that demands be specified in a consistent way. In particular, it is necessary to weight each demand by the fraction of the cycle over which it prevails. Thus, demand is expressed as $D_i^{(w_i)}$, where i refers to the subperiod in question and superscript (w_i) to the fraction of the cycle during which the demand in question prevails, with each demand curve showing the amount of output per cycle which would be demanded at every price were the demand in question to prevail over the entire cycle. This permits us to handle subperiods of unequal duration, whereas equal-length subperiods are all that are explicitly dealt with (and appear to be implicit where the length of period is not stated) in earlier analyses. Thus our formulation is more general in this respect than those which have been developed previously. In order to simplify the analysis we make the conventional assumption that each periodic demand is independent. Whether or not this is a reasonable assumption is, of course, an empirical question. In circumstances where time patterns of consumption are relatively inflexible, the independence assumption is presumably a close approximation.

We assume divisible plant initially and consider the two-period case with an off-peak load of length 8 hours and a peak load of 16 hours, so that demand is expressed as $D_1^{(1/3)}$ and $D_2^{(2/3)}$, respectively. These demand conditions, together with the cost relations specified above, are shown in Figure 2.

Solving for the optimum plant size geometrically requires that we develop a technique for combining the individual periodic-load curves to obtain an over-all "effective demand for capacity" relation. For this purpose we note that, taking each periodic load by itself and assuming that the plant is operated only for the one load and is shut down during the remainder of the cycle, the price charged in the interval during which the plant is operated must be $b + \beta/w_i$ (where w_i is the fraction of the cycle during which load i prevails) in order that enterprise net revenue be zero. That is, under the conditions described, total revenue from operations will be $P_i Q_i w_i$, total costs will be $b Q_i w_i + \beta Q_i$, and only if $P_i = b + \beta/w_i$ will total revenue less total costs yield the zero net revenue

P

FIGURE 2

result. Since this latter condition necessarily holds in long-run equilibrium in a system with constant returns to scale and divisible plant, clearly the price of $b + \beta/w_i$ is correct. We want now to construct a demand-for-capacity curve for each periodic-load curve which has the property that it intersects the long-run marginal cost curve at the capacity level Q_i corresponding to the price $b + \beta/w_i$. If such a curve can be obtained by a simple transformation of the periodic-load curve, the appropriate capacity (and consequently price) can be found directly rather than through the indirect process described above.

A curve with these properties can be constructed by taking the vertical difference between the periodic-load curve and short-run marginal

costs (b), multiplying this difference by the fraction (w_i) of the cycle during which the periodic load in question prevails, and adding vertically this weighted demand-for-capacity curve to the short-run marginal cost curve. The resulting curve intersects $b+\beta$ at precisely the value of Q_i for which $P_i = b+\beta/w_i$ on the corresponding periodic-load curve. Extending the analysis so as to obtain an over-all demand-for-capacity curve requires that we combine the contributions to capacity made in every subperiod. This is accomplished by adding vertically to the short-run marginal cost curve the vertical summation of the individual weighted demand-for-capacity curves (obtained according to the procedure described above). The resulting effective demand-for-capacity curve for $D_1^{(1/3)}$ and $D_2^{(2/3)}$ is shown as D_E in Figure 2. It will be noted that D_E is kinked at F , which corresponds to output level Q_{12} , since for outputs that exceed Q_{12} the demand price along the off-peak-load curve is everywhere below $SRMC$. That this construction is correct and leads to a set of results that parallel those obtained for the uniform-load analysis in Section II can be seen by considering the solutions that obtain under two different values of capacity cost (β_1 and β_2) in Figure 2.

For $\beta = \beta_1$ the $LRMC_1$ intersects the demand-for-capacity curve D_E at B , so that the optimum scale is Q_1^* . $SRMC_1$ is horizontal at level b from O to Q_1^* and is vertical thereafter. Thus the appropriate output in each subperiod is Q_1^* , with the price being P_{11} in the off-peak-load period and P_{21} at peak load. Total revenue is given by $P_{11}Q_1^*(\frac{1}{3}) + P_{21}(Q_1^*)(\frac{2}{3})$ while total cost is $(b+\beta_1)Q_1^*$. That these must be equal is seen by observing that for any value of β_1 for which the corresponding $LRMC$ curve intersects D_E anywhere in the range AF , and assuming that capacity is optimally adjusted and that P_{11} and P_{21} are chosen so as to equate $SRMC_1$ and demand price, the following relation will hold: $(b+\beta_1) - P_{11} = 2[P_{21} - (b+\beta_1)]$. Thus, the amount by which revenues in the off-peak-load period fail to cover pro rata total costs is precisely offset by revenues in the peak-load period in excess of pro rata total costs. Put differently, net revenue is identically zero in this system with completely divisible plant so long as (1) the intersection of the demand-for-capacity curve and the long-run marginal cost curve is used to define plant capacity and (2) prices in each period are set at the level at which the short-run marginal cost curve intersects the respective periodic-load demand curve. Our construction of D_E guarantees this result.

Consider now a capacity cost of β_2 per unit per period. $LRMC_2$ now intersects D_E at G , so that the optimum scale is Q_2^* . $SRMC_2$ is horizontal at level b from O to Q_2^* and then moves vertically upward. The appropriate prices and outputs, therefore, are P_{12} ($=b$) and Q_{12} in the off-peak period, and P_{22} , Q_2^* during peak load. The revenues and operating costs during the off-peak load are equal. Thus revenues during peak load must

be sufficient to cover both operating costs and the entire capital charge if zero net revenues are to be realized. Again, our construction of the effective demand-for-capacity curve, D_E , assures this result. To see this, we observe that, by virtue of this construction, P_{22} necessarily equals $b + (3/2)\beta_2$ at Q_2^* . Therefore revenue during peak load is $(b + 3/2\beta_2)Q_2^* \cdot 2/3$, or $(2/3)(bQ_2^* + \beta_2Q_2^*)$. Operating cost during peak load is $(2/3)(bQ_2^*)$. Hence the excess of revenue over operating cost during peak load is $\beta_2Q_2^*$, which is the capacity cost per cycle, and zero net revenue results.

That positions B and G are optimal as claimed can also be seen by considering the effect on welfare of an incremental change in Q_1^* and Q_2^* , respectively. An increase in scale leads to a decrease in producers' surplus that exceeds the gain in consumers' surplus; a decrease in scale yields an increase in producers' surplus that is less than the loss of consumers' surplus. This can be judged by reference to either the D_E curve or the individual load curves taken separately.

The problem can also be formulated algebraically and identical results obtained. Using subscripts 1 and 2 to refer to off-peak and peak-load demands, respectively, and w_1 and w_2 as the corresponding fraction of a cycle accounted for by each (and $w_1 + w_2 \leq 1$, with the equality holding unless there is a third period in the cycle during which plant is shut down altogether), we have as our periodic-load counterpart of (1)

$$(9) \quad W = (TR_1 + S_1)w_1 + (TR_2 + S_2)w_2 - bQ_1w_1 - bQ_2w_2 - \beta_2Q_2.$$

The objective is to find the pricing rule in each subperiod and the optimum capacity, Q_2 . If, as in case 1 described above, plant is utilized to capacity during both off-peak and peak-load periods, we have $Q_1 = Q_2$. Letting $Q = Q_1 = Q_2$, optimum plant size is obtained by differentiating

$$(9') \quad W = (TR_1 + S_1)w_1 + (TR_2 + S_2)w_2 - bQ(w_1 + w_2) - \beta_1Q$$

with respect to Q . Thus we obtain:

$$(10) \quad \frac{\partial W}{\partial Q} = P_{11}w_1 + P_{12}w_2 - b(w_1 + w_2) - \beta_1 = 0$$

or

$$P_{11}w_1 + P_{12}w_2 = b(w_1 + w_2) + \beta_1.$$

Letting $w_1 = 1/3$ and $w_2 = 2/3$, this is precisely the result obtained from our geometry in Figure 2 for the case where $\beta = \beta_1$.

If instead plant is utilized to capacity only under peak-load demands, we have by differentiating (9) partially with respect to Q_1 and Q_2 :

$$(11) \quad \frac{\partial W}{\partial Q_1} = P_{21}w_1 - bw_1 = 0$$

or

$$P_{11} = b$$

$$(12) \quad \frac{\partial W}{\partial Q_2} = P_{22}w_2 - bw_2 - \beta_2 = 0$$

or

$$P_{22} - b = \frac{\beta_2}{w_2}.$$

These are precisely the results obtained from our analysis of Figure 2 for $\beta = \beta_2$. Thus price in the off-peak interval is set equal to short-run marginal cost. The price during peak load is set at incremental operating cost (b) plus incremental capacity cost (β_2) divided by the fraction of cycle time accounted for by peak load (w_2).¹⁰

The multiperiod generalization of equations (9)–(12) is both easy and obvious. The welfare function in this instance becomes

$$W = \sum_{i=1}^n (TR_i + S_i)w_i - \sum_{i=1}^n bQ_iw_i - \beta Q^*,$$

where Q^* refers to optimum system capacity. Optimality requires that $P_i = b$ in those periods when plant is not utilized to capacity and, letting I be the subset of periods when capacity is fully utilized,

$$\sum_{i \in I} (P_i - b) w_i = \beta$$

By way of summarizing the argument, we have as basic principles for dealing with periodic demands (assuming that costs and demands are defined as suggested above):

- A. Optimal plant size (assuming fully divisible plant) is given by the intersection of the *LRMC* curve and the effective demand-for-capacity curve.
- B. Optimal price in every subperiod is given by the intersection of the *SRMC* curve and the subperiod demand curve.

¹⁰ If, as in Section I, we take capacity as given by the constraint \bar{Q} and formulate the welfare-maximization problem as a Lagrangian, the parallel results to those obtained in equation (7) are:

- (i) if $Q_1 = Q_2$ (the case where $\beta = \beta_1$)

$$P_{11}w_1 + P_{12}w_2 = b + \lambda_1,$$
- (ii) if $Q_1 < Q_2$ (the case where $\beta = \beta_2$)

$$P_{11} = b$$

$$P_{22} = b + \frac{\lambda_1}{w_2}.$$

Again, λ_1 is the shadow price associated with the constraint, and if $\lambda_1 > \beta_1$ an expansion is signaled whereas if $\lambda_1 < \beta_1$ a contraction is indicated.

C. In a fully adjusted, continuously utilized system with only two periodic loads:

- (a) Peak-load price always exceeds *LRMC*.
- (b) Off-peak-load price is always below *LRMC*.
- (c) Only when the off-peak load fails to use plant to capacity when priced at *SRMC* does the peak load bear the entire burden of the capacity costs.

Before extending the analysis to deal with indivisible plant, we consider first how our approach differs from those of Boiteux, Steiner, and Hirshleifer. With respect to Boiteux, the principal difference is that he uses only equal-length subperiods (both in his geometry and [apparently] in the appendix) and hence there is a lack of generality in his results. Although he solves the optimum pricing problem for the two-period case both geometrically and analytically, he lacks a device for aggregating periodic loads geometrically and thus solves the optimum capacity problem only analytically (and only for the special case of equal-length-subperiod loads).

Steiner and Hirshleifer each employs a geometric technique that correctly handles the peak-load capacity and pricing problem for the case of two equal-length-subperiod loads. Instead of using a weighted average of subperiod demands to obtain an effective demand-for-capacity curve in the way we have done, they sum the periodic loads vertically. This technique, together with the way in which they define their costs in order to support the technique, suggests that the periodic-load problem requires rather unconventional apparatus for its solution. It thus appears that the solution to the periodic-load problem is something other than a simple generalization of the usual uniform-load results. In addition, both Steiner's geometric treatment of the three-period case [7, pp. 590-91] and Hirshleifer's verbal generalization to the n —(equal length) period case [3, pp. 456-57] require that capacity costs be redefined for each condition. It is obvious, however, that capacity costs *per cycle* are independent of the number of subperiods included, and expressing costs in terms of the cycle, as we have, rather than for the subperiod, as they do, avoids this respecification problem. Moreover, since neither explicitly indicates the necessity for this respecification, uncritical implementation of their results easily leads to error.¹¹

¹¹ Consider, for example, what seems to us the "natural" interpretation of Hirshleifer's argument. For the two-period case he observes that "If the demand price . . . for a single period alone did exceed $b + \beta$, an increase in capacity is obviously called for" [3, p. 456]. Generalizing to the n -period case he states that "more capacity should be added if . . . [in any of the n -periods] the demand [price] for *any* single period alone . . . exceeds $b + \beta$ " [3, p. 457 (*italics added*)]. In the absence of explicit instructions to the contrary, the standard presumption is that the specification of β in both citations is identical. But, assuming that both statements are correct, this is clearly impossible. Thus suppose that demand price exceeded $b + \beta$ in only one of the subperiods in both the two-period and n -period cases and that during the remainder of the

Consider now the extension of our analysis to deal with indivisible plant. Replacing the assumption of fully divisible plant by one in which indivisibilities are present is made easy by our construction of an effective demand-for-capacity curve. Using this device, our analysis in Section II applies directly. Thus the criterion for shifting from Q_1^* to $Q_1^* + E$ is identical to that shown in Figure 1: whenever the triangular area defined by Q_1^* , the effective demand-for-capacity curve, and the *LRMC* exceeds the area within $Q_1^* + E$, the D_E curve, and *LRMC*, the additional efficiency unit should be installed. The conditions under which one would be just indifferent between adding the capacity or not are shown in Figure 3.

Again we assume that the off-peak load prevails for $1/3$ of the cycle and the peak load for $2/3$, D_E being the weighted sum of $D_1^{(1/3)}$ and $D_2^{(2/3)}$. By construction, $IJN = JKL$, so that the benefits of installing the additional efficiency unit are just offset by the costs. In terms of the individual demand curves, the following relation holds: $2/3(NFG) - 2/3(GKH) - 1/3(MNKO) = 0$, where $2/3(NFG - GKH)$ is the amount by which the increase in consumers' surplus that is realized by adding the new capacity exceeds the loss in producers' surplus during peak-load operations (assuming that demand is supplied at *SRMC* prices both before and after), and $1/3 MNKO$ is the amount by which the additional consumers' surplus falls short of the loss in producers' surplus during off-peak operations.

All of the implications that were developed in Section II concerning the effects of indivisibilities, including those that were obtained in connection with variable demand, likewise apply to the analysis of periodic demand. One additional comment, however, might be useful.

It will be noted that peak-load price in Figure 3 after installation of the new efficiency unit is less than *LRMC*. This appears to contradict our proposition C(a) given earlier. Actually, however, there is no inconsistency; the circumstances are different between Figures 2 and 3—the difference of course is that fully divisible plant is no longer assumed, whereas it was previously. Optimally adjusted plant under the assumptions of constant returns to scale and complete divisibility leads to zero

cycle capacity is never reached, so that service is supplied at the short-run marginal cost price of b . Thus the only contribution to capacity costs in each case occurs during the one subperiod when price exceeds b . Letting capacity be Q^* , the net revenue over operating costs is βQ^* ($1/2$) for the two-period case and βQ^* ($1/n$) for the n -period case, assuming that each of the n periodic loads is of equal length. Obviously if capacity costs are covered for the two-period problem they can not be for the n -period case. Hence the presumption that β is the same in both the two-period and n -period cases must be replaced by one in which, if β_2 is the capacity cost in the two-period case and β_n in the n -period case, $\beta_n = n/2 \beta_2$. Given this respecification, Hirshleifer's optimality rules are correct, but not otherwise. Since both he and Steiner fail to indicate that such a respecification is necessary, the possibility that their prescriptions would lead to error can hardly be dismissed.

FIGURE 3

profits and, necessarily, peak-load price will exceed $LRMC$. The optimally adjusted plant when indivisibilities are present, however, will only accidentally lead to zero profits. Thus, if demand is $D_E + \epsilon$, the optimal plant size is $Q_1^* + E$, and although P_2 may exceed $LRMC$, it need not (and indeed does not in the circumstances shown in Figure 3).

IV. Conclusions

Although we have hardly disposed of all of the interesting questions that relate to the optimal pricing of periodic loads, we believe that the approach employed tends to clarify the issues in a useful way and readily lends itself both to specific application and to possible extensions. By

explicitly introducing a social welfare function at the outset we attempt to emphasize that the choice of optimal size plant and the pricing of services from plant of given capacity are not special problems at all but are merely particular applications of a perfectly general welfare formulation. Thus a good deal of the mystique which has tended to surround the analysis of peak-load pricing can be dispelled at the outset. This approach has the further advantage that we can interpret in welfare terms each of our results as they are derived and thereby provide a more convincing rationale for the results than merely arguing that they come from "straightforward maximization techniques."

That the analysis of periodic loads differs only in degree and not in kind from the more commonly investigated uniform-load problem is made particularly evident by our use of the "effective demand for capacity curve" device. By carefully defining our cost and demand relationships in advance, any periodic-load problem can be reduced to a demand-for-capacity analysis for purposes of selecting optimal plant size, and this holds whether we deal with completely divisible or indivisible plant. The optimal capacity criterion is identically the same in each case. Pricing to periodic loads and to uniform loads similarly follow the same pricing criterion: equate short-run marginal cost to demand price. Each periodic load must be priced separately, however; our weighted average demand curve is relevant only for long-run optimality (plant size) adjustments.

Possible extensions of our analysis would presumably include relaxing the assumption that demands in each period are independent. It is unlikely, however, that a useful geometry can be devised to deal with this more general case. Likewise it may be desirable to qualify the proposition that continuously equating short-run marginal cost to demand price is optimal. As Boiteux has pointed out, it may be useful for customer planning purposes to follow a more stable pricing policy [1, pp. 70-72]. However, Boiteux's proposal that "Whatever the capacity of existing plant, *the need to keep prices steady* generally leads prices to be fixed as if the plant were of optimum size" [1, p. 72] itself appears to be suboptimal. Rather, optimality requires that the benefits of pricing according to short-run marginal cost (the pricing rule that obtains under our welfare formulation) be weighed against the benefits of Boiteux's stable price proposal and an appropriate balance struck. For this purpose, a more broadly conceived social welfare function that makes explicit the gains to be secured through price stability is required. The trade-off between the short-run benefits of price flexibility and the long-run benefits of stability can then, presumably, be optimally arranged.

Generalizing the analysis to deal with nonlinear costs might also seem useful. This is easily accomplished analytically, but our geometry fails to

apply in this instance. Under the assumption of long-run constant returns to scale, so that the *LRMC* curve remains horizontal and only the short-run cost curves display curvature, the nonlinear case yields results qualitatively similar to those obtained above.¹² Since the analysis of unequal-length periodic loads with nonlinear costs is somewhat more involved, does not lend itself to treatment geometrically, and fails to produce insights that differ appreciably from those obtained from the linear model, there are obvious advantages, for purposes of explicating the peak-load problem, in using the simpler linear form.

The relevance of the analysis to problems other than electricity generation might also be indicated. The optimality principles derived above regarding capacity and pricing of electricity apply to any public service which our welfare formulation and cost and demand specifications properly embrace. This would presumably include the investment in and operation of transportation facilities (airports, public surface transportation, bridges, etc.), recreation facilities, natural gas transmission, etc. Since the bridge problem is one of such long-standing interest, yet remains the source of continuing confusion, an application of the analysis to this question might be particularly useful. The major cause for misunderstanding here is the failure to distinguish between circumstances where capacity is a parameter from those in which it is a variable. Optimal pricing for a facility of *specified* capacity is given by the rules shown in equation (7) and footnote 10. As is obvious from inspection of these relations, if (for whatever reason) an oversized bridge is "inherited," so that the value of λ_i in these expressions is zero or negligible, and if operating costs are also so small that they can be disregarded, a zero use charge will be optimal. If, however, capacity is a variable rather than a

¹² The nonlinear cost problem can be formulated as: maximize,

$$W = \sum_{i=1}^n (TR_i + S_i)w_i - \sum_{i=1}^n (TVC_i)w_i - \beta Q^*.$$

Differentiating partially with respect to Q_i , we obtain n equations of the form

$$P_i = SRMC|_{Q_i},$$

and differentiating with respect to Q^* , we have

$$\beta = - \sum_{i=1}^n \frac{\partial}{\partial Q^*} (TVC_i)w_i.$$

Thus price in every period is set equal to short-run marginal cost, and capacity is extended until the weighted average marginal change in operating costs is equal to the marginal capacity cost, β .

It should be noted that Hirshleifer solves geometrically the case of nonlinear costs with constant returns to scale for the problem of identical-length-subperiod load by employing Steiner's vertical summation procedure [3, pp. 452-57]. We also point out that, as anyone familiar with the Hirshleifer-Steiner dispute over the interpretation of marginal costs as they apply to the economics of peak-load pricing will recognize, we agree with Hirshleifer that the solution does not involve discriminatory prices.

parameter so that facility size can be adjusted (and indivisibility constraints aside), optimal pricing and optimal plant size are given by the relations shown in Figure 2 and equations (10)–(12). Even with zero operating costs, a positive use charge will be required here since, with capacity correctly selected, a positive price will be needed to ration capacity between those activities for which marginal benefits are high and those for which it is low. Assuming constant returns to scale, optimal pricing to this fully adjusted facility will yield precisely zero net revenues, and the bridge in these circumstances will be self-supporting. This latter, however, has no special normative significance. If there are indivisibilities, if increasing or decreasing returns to scale exist, or if capacity is given rather than subject to determination, optimal pricing will yield the zero net revenue result only accidentally if at all.

MULTIPERIOD FUTURE CONSUMPTION AS AN AGGREGATE

By NISSAN LIVIATAN*

The two-dimensional analysis of the optimal allocation of the consumer's wealth between present and future consumption in a two-period model is presented in most modern textbooks by means of the well-known diagram of Irving Fisher. However, when Fisher considered the possibility of extending his diagram to a multiperiod analysis he commented: "The truth seems to be that no complete visualization of this difficult problem is possible. The only complete symbolization which seems to be possible is in terms of mathematical formulas" [3, p. 287].¹

While in general Fisher is right with respect to the *complete* visualization, the question arises as to how far one can go by using a simple two-dimensional diagram. After all we are often not interested in the determination of consumption in *every* future period but rather in the determination of *current* consumption and *current* capital accumulation. The purpose of this note is accordingly to analyze the conditions under which it is possible to break down the complicated problem of multiperiod planning into a problem of allocating consumer resources between present and future consumption where the latter is represented by a single quantity. When this is possible we may analyze the relevant problems by the ordinary two-dimensional indifference-map technique.

More specifically, the multiperiod consumer is supposed to maximize a utility function $U(C_0, C_1, \dots, C_n)$, where C_t denotes planned consumption for period t , subject to his wealth constraint.² The optimal values of all the C_t 's obviously cannot be determined by a two-dimensional analysis. We may pose however the following question: under what conditions is it possible to represent the stream of future consumption C_1, \dots, C_n by a single "good" (say X) and to form a utility function [say $V(C_0, X)$] which can be maximized subject to a two-dimensional wealth constraint (involving only C_0 and X as endogenous variables) so as to yield the correct optimal value of C_0 (and, indirectly, of current capital accumulation). By "correct" I mean of course that value of C_0 which would result from maximizing the completely specified utility function $U(C_0, C_1, \dots, C_n)$ subject to the relevant ($n+1$ dimensional) wealth constraint. A basic problem which arises in this connec-

² C_t is assumed to be, physically or economically, a single good which accounts for total consumption in period t .

tion is whether the two-dimensional system remains valid under changes in various exogenous parameters.

In our analysis special consideration will be given to two recently suggested measures which can essentially be interpreted as representing multiperiod future consumption by a single variable. One measure is that of Leontief [7, p. 105], who represents the "future" by the perpetual (equal) stream of future consumption, and the other measure is that of Dewey [1, p. 134], who represents it by the wealth which is planned for the next period. Although these measures have an intuitive appeal, it is by no means clear that we may use them under all circumstances. Indeed we shall show that under fairly common variations in external conditions these measures become economically meaningless. At the same time we shall point out some important cases where the foregoing measures *are* meaningful. In particular we shall show that it is possible to provide a rigorous theoretical justification for aggregation over future consumption in the models considered by Leontief and Dewey.

I. Exogenous Interest Rates

Consider an individual consumer in a market economy who has a given amount of wealth W which he plans to consume over $n+1$ periods. As before, denote the planned values of consumption by C_0, C_1, \dots, C_n . If necessary, C_n may be thought of as the terminal stock of wealth which the consumer plans to bequeath or to carry over beyond the planning horizon. It is assumed that the consumer is faced with fixed (exogenous) interest rates between any two consecutive periods, denoting the interest rate between period $t-1$ and t by r_t . We may then easily compute the "price" (or transformation rate), say P_t , of consumption in period t , in terms of current consumption C_0 . Clearly we have:

$$(1) \quad P_0 = 1, P_1 = \frac{1}{1+r_1}, P_2 = \frac{1}{(1+r_1)} \frac{1}{(1+r_2)}, \dots, \\ P_n = \frac{1}{(1+r_1)} \frac{1}{(1+r_2)} \dots \frac{1}{(1+r_n)}.$$

(In the special case where all r_t 's are equal (1) reduces to $P_t = 1/(1+r)^t$.) Using this notation, the consumer's budget constraint is given by:

$$(2) \quad W = P_0 C_0 + P_1 C_1 + \dots + P_n C_n.$$

The conditions under which we may aggregate over C_1, \dots, C_n are of two kinds: those which restrict the variation of the interest rates and those which restrict the form of the utility function. We begin with the former. Suppose that we consider situations where the r_t 's, and hence also the P_t 's, remain constant throughout the analysis. We shall indicate

these constant values by adding a zero superscript to r_t and P_t , writing r_t^0 and P_t^0 . In this case we may apply Hicks's composite-good theorem [6, pp. 33-34 and 312-13] which states that a group of commodities with fixed relative prices can be treated as an ordinary individual commodity. We may then define

$$F = \sum_{i=1}^n P_i^0 C_i$$

as our composite good (the price of which is unity) and draw the usual type of indifference curves in the (C_0, F) plane, corresponding to a utility function $V(C_0, F)$, and ordinary budget lines, corresponding to $W = C_0 + F$. By Hicks's theorem this "reduced system" can be used to determine the correct optimal values of C_0 and of capital accumulation³ $r_1^0 W - (1 + r_1) C_0$. It is clear that the foregoing reduced system can be used to analyze the *income* effect⁴ of a change in W on C_0 . This is in fact the main theoretical use of the reduced system since, as we shall see, it cannot generally be used to study the effects of a change in the rate of interest.

It may be noted that

$$F = \sum_1^n P_i^0 C_i$$

is the "present value of future consumption"⁵ which is the same thing as the "present value of planned wealth for the next period." Alternatively, we are free to define our composite good as

$$F^{(1)} = (1 + r_1^0) F = \frac{F}{P_1^0}$$

i.e., as "planned wealth for the next period" (valued as of that period) which coincides with Dewey's measure. The latter procedure is legitimate since we are allowed to multiply a Hicksian composite good by a constant $(1 + r_1^0)$ provided, of course, we adjust its price accordingly.

³ This is defined as the difference between W in the next period and in the present period, when consumption takes place in the *beginning* of any period. The value of consumption which leads to a zero accumulation, i.e., $r_1^0 / (1 + r_1^0) W$, can be properly called "permanent income."

⁴ In some cases this is our primary interest. For example in the presentation of his consumption theory Friedman's main concern is to show how C_0 varies as a result of a change in the consumer's wealth. (See Friedman [4].) In view of our analysis there is no need in such cases to restrict oneself, as Friedman does, to a two-period graphical analysis [4, pp. 8-10].

⁵ Note that

$$\sum_1^n P_i^0$$

is the present value of an annuity of one dollar for n periods, beginning with the next period.

Thus if we work with $F^{(1)}$ its "price" will be $1/(1+r^0)$, and the budget line will be

$$W = C_0 + \frac{1}{1+r^0} F^{(1)}$$

When all r_t 's are equal we may, by the foregoing reasoning, define a composite good $F^{(2)} = rF [= r(W - C_0)]$, which is the Leontief measure of the potential⁶ constant stream of future consumption which can be maintained indefinitely starting from the next period. The budget line is then given by $W = C_0 + (1/r)F^{(2)}$. Thus Dewey's and Leontief's measures are legitimate for the present case.

Suppose now we wish to analyze the effect of a change in interest rates on C_0 or on capital accumulation within the framework of a reduced system including only C_0 and some composite good to represent future consumption. Suppose first that all r_t 's are equal, so that $P_t = 1/(1+r)^t$. When r changes, every P_t will change in a different proportion. Alternatively, the relative price, say $P_{t-1}/P_t = 1+r$, must change. Since the relative prices of the C_t 's ($t=1, \dots, n$) must change, the foregoing composite goods ($F, F^{(1)}, F^{(2)}$) become economically meaningless. A two-dimensional analysis must therefore be ruled out.

Let us return to the case where the r_t 's may differ for various periods. Is it then possible to vary the r_t 's in such a way as to leave the ratios of the P_t 's ($t=1, \dots, n$) constant? When this is possible, we may still have a true composite good to represent the future, under appropriate variations in the r_t 's. At first glance it may seem that there are many ways of varying the r_t 's so as to leave the ratios of the P_t 's ($t=1, \dots, n$) unchanged. However a closer examination will reveal that there is only a single way of accomplishing this, namely by changing only r_1 , leaving all other r_t 's ($t=2, \dots, n$) unchanged. This follows from the special form in which the P_t 's are related to the r_t 's by means of equation (1). Suppose, e.g., that we change r_2 . Then $P_1/P_2 = 1+r_2$ changes, so that relative prices are no longer constant. This will remain true for a change in any r_t , or in a combination of r_t 's, when $t=2, \dots, n$. If, however, we change only r_1 , then all the relative prices for any pair of P_t 's ($t=1, 2, \dots, n$) will remain unaffected since $1/(1+r_1)$ is a common factor of all these P_t 's

$$\left(P_t \text{ being given by } \frac{1}{1+r_1} \frac{1}{1+r_2} \dots \frac{1}{1+r_t} \right).$$

⁶ Note that this measure has nothing to do with the planned optimal *distribution* of consumption in future periods. Note also that although this measure refers to an infinite stream there is no need at all to assume that the actual planning horizon for consumption (i.e. the one on which P is based) is infinite too.

We may consider the foregoing case as one where the elasticity of expectations with regard to a change in r_1 is zero (since it does not affect the values of the future r_t 's). For this case we may define our composite good as

$$F^* = \sum_1^n P_t^0 C_t,$$

where

$$P_t^0 = \frac{1}{1 + r_1^0} \frac{1}{1 + r_2^0} \cdots \frac{1}{1 + r_t^0}$$

and where the zero superscripts denote the initial set of parameters (r_t 's and P_t 's). This is equivalent to the valuation of a Hicksian composite good in terms of constant "base point" price. Since we permit changes in r_1 only, the "current" (variable) prices become

$$P_t = \frac{1}{1 + r_1} \frac{1}{1 + r_2^0} \cdots \frac{1}{1 + r_t^0}.$$

The price (P) of the composite good F^* is then

$$P = \frac{P_t}{P_t^0} = \frac{1 + r_1^0}{1 + r_1} \quad (t = 1, \cdots, n),$$

which satisfies the "value identity"

$$PF^* = \sum_1^n P_t C_t$$

(noting that $P_t = PP_t^0$). The budget line is then given by $W = C_0 + PF^*$ and we may carry out the usual two-dimensional analysis with C_0 and F^* as our commodities. In this particular case we may analyze in two dimensions not only the effect of a change in W , but also a change in the rate of interest provided the latter is confined to a change in r_1 only.

This is as far as we can go when our restrictions relate to interest rates only. We may however consider restriction on the utility function itself. In particular suppose that the utility function $U(C_0, C_1, \cdots, C_n)$ can be written as a "separable" function $U[C_0, H(C_1, \cdots, C_n)]$ where in turn $H(\quad)$ is a linear homogeneous function in C_1, \cdots, C_n . It may be noted that the foregoing separability and homogeneity assumptions are perhaps not as unrealistic when applied to a utility function which deals with *aggregate* consumption in various periods in contrast with one which deals with *individual* categories of consumption (food, clothing, etc.). In this connection we may also note that the assumption that the

utility function is homogeneous in the C_t 's (including C_0) is the basis of some well-known modern consumption theories.⁷ Now, it has been shown [5, Ch. 4] that when the utility function is separable and homogeneous in the foregoing manner, then there exists an ideal price deflator⁸ $\bar{P}(P_1, \dots, P_n)$ for "money outlay"

$$\sum_1^n P_t C_t,$$

so that we may form a reduced utility function $Q(C_0, D)$ where

$$D = \frac{\sum_1^n P_t C_t}{\bar{P}(P_1, \dots, P_n)} \equiv H(C_1, \dots, C_n).$$

If we work with $Q(C_0, D)$ and with budget lines $W = C_0 + \bar{P}D$, then we shall be able to determine the correct optimal values of C_0 and D (which implies that we can determine correctly the optimal value of

$$\sum_1^n P_t C_t$$

and hence also of capital accumulation).

We must stress, however, that aggregation under the foregoing restrictions on the utility function is of very limited use. The difficulty stems from the fact that the slope coefficient of the budget line $\bar{P}(\)$ depends not only on the P_t 's (or r_t 's) but also on the specific form of the function $H(C_1, \dots, C_n)$ above (as can be seen from the example given in footnote 8). In other words, the slope of the budget line at some set of interest rates depends on the consumer's tastes. Consequently we cannot know in general what will be the effect of a change in r_t on \bar{P} without knowing the consumer's tastes. This rules out effectively the possibility

⁷ Namely Friedman's "Permanent Income Hypothesis" and Modigliani's "Life Cycle Hypothesis." See M. Friedman [4] and F. Modigliani and R. Brumberg [8].

⁸ $\bar{P}(P_1, \dots, P_n)$ is a linear homogeneous function in the P_t 's. If, e.g., $H(C_1, \dots, C_n)$ is of the form

$$C_1^{a_1} C_2^{a_2} \dots C_n^{a_n},$$

then $\bar{P}(\)$ will be of the form

$$\bar{P} = \left(\sum_1^n a_t \right) \left(\frac{P_1}{a_1} \right)^{\frac{a_1}{\sum_1^n a_t}} \left(\frac{P_2}{a_2} \right)^{\frac{a_2}{\sum_1^n a_t}} \dots \left(\frac{P_n}{a_n} \right)^{\frac{a_n}{\sum_1^n a_t}}$$

where the summation is always from 1 to n . This example has been taken from an article by R. Solow on a different problem which can however be related to the present one. See R. Solow [9, p. 105].

of analyzing the effect of a change in r_t on C_0 and on capital accumulation. The only changes we can analyze in this case are changes in wealth (where the slope of the budget line remains unchanged). But as we have seen, in order to analyze changes in wealth we do not need to impose *any* restrictions on the utility function. Thus, while it is true that with a separable and homogeneous utility function we have perfect quantity and price indexes for aggregative future consumption, these indexes (and their underlying assumptions) are not required for the analysis of wealth effects, and are not sufficient for the general analysis of changes in the r_t 's.

II. The "Robinson Crusoe Economy"

There exists a tendency to apply some version of Fisher's apparatus to deal with the economy as a whole on the assumption that we are permitted to use community indifference curves and some simple type of an aggregative production function. Thus, for example, both Leontief and Dewey were concerned with a model of the foregoing kind. Clearly, this set of assumptions amounts to considering a one-man ("Robinson Crusoe") economy. Let us now examine the possibility of aggregation over future consumption (C_1, \dots, C_n) within the framework of such an economy. First let us formulate the model more accurately.

On the consumption side we consider an individual ("Robinson Crusoe") whose preferences for alternative collections C_0, C_1, \dots, C_n are ordered by a utility function $U(C_0, C_1, \dots, C_n)$. Turning to the production side we assume that there exists a homogeneous good which can be used both as a present consumption good and as an input to produce next period's consumption. The quantity of this good at the beginning of any period (t) will be denoted by K_t and referred to as "capital in period t ." We assume a simple Ramsey-type production function:⁹

$$(3) \quad K_{t+1} = f(K_t - C_t); \quad t = 0, 1, \dots, n-1,$$

which shows how the unconsumed part of capital at any period can be used to produce the (net) initial capital stock of the next period. Ordinarily we assume $f'(\) > 0$, $f''(\) < 0$, i.e., the marginal product of $K_t - C_t$ is positive and decreasing. It may be assumed, without affecting the argument, that there is a constant amount of labor input (for all t) cooperating with capital. It will be convenient to identify the terminal capital stock K_n with C_n since it is either consumed or "bequeathed." In any case K_n represents a "final use" within the framework of this model and has therefore to enter the utility function as do the other C_t 's.

We may now derive the transformation function between the C_t 's as

⁹ This type of production function is implicit in Dewey's paper and is used often elsewhere. See, e.g., R. Dorfman and others [2, pp. 271-76].

follows. Write (3) in full as

$$(4) \quad K_1 = f(K_0 - C_0); K_2 = f(K_1 - C_1); \dots; C_n = f(K_{n-1} - C_{n-1}).$$

Substitute successively (working from left to right) the right-hand side of each equation in (4) into the following one. This will eliminate all K_t 's except for K_0 and will lead to a transformation function

$$(5) \quad T(C_1, \dots, C_n; K_0) = 0$$

with K_0 as a parameter. This function shows all possible collections which can be produced starting with a given value of initial capital. If, for example, we set $n=3$ we have

$$(6) \quad T(C_0, C_1, C_2, C_3; K_0) \equiv C_3 - f\{f[f(K_0 - C_0) - C_1] - C_2\} = 0.$$

The difference between the present model and the one in Section I is that now the marginal rates of transformation (MRT) between the C_t 's are no longer constant, but rather vary with their quantities. The MRT between C_0 and C_1 can be calculated as follows. Given the initial K_0 and some specified set C_0, C_1, \dots, C_n , we can determine via (4) the values of all K_t ($t=1, \dots, n-1$). It follows that all the arguments of the functions in (4) are determined. Suppose now we wish to calculate the MRT between C_0 and C_1 . If the consumer gives up one unit of C_0 he may increase C_1 (holding all other C_t 's constant) by the marginal product $f'(K_0 - C_0)$. The negative of the latter is therefore the required MRT. Similarly a sacrifice of one unit of C_0 can increase C_2 (holding C_1, C_3, \dots, C_n constant) by $f'(K_0 - C_0)f'(K_1 - C_1)$, which is the MRT (in numerical value) between C_0 and C_2 . In general,¹⁰ the MRT between C_q and C_0 is given by the product

$$-f'(K_0 - C_0)f'(K_1 - C_1) \dots f'(K_{q-1} - C_{q-1}).$$

¹⁰ Alternatively, differentiate the system (4) w.r.t. C_0 and C_q holding all other C_t 's (and K_0) constant. If $q < n$, then for $t=n$ this leads to

$$dC_n = f'(K_{n-1} - C_{n-1})dK_{n-1} = 0,$$

since $dC_n = 0$ by assumption. However, since $f' > 0$, this implies $dK_{n-1} = 0$. Using this result and applying similar reasoning we find that $dK_t = 0$ for $t=q+1, \dots, n-1$. However $dK_{q+1} = f'(K_q - C_q)$. ($dK_q - dC_q = 0$ implies $dK_q = dC_q \neq 0$). Hence

$$dC_q = dK_q = f'(K_{q-1} - C_{q-1})dK_{q-1} \neq 0.$$

Similarly

$$dK_t = f'(K_{t-1} - C_{t-1})dK_{t-1} \neq 0$$

for $t=2, \dots, q-1$. Finally,

$$dK_1 = -f'(K_0 - C_0)dC_0.$$

By successive substitution we eliminate the dK_t 's and obtain (for $q=1, \dots, n$):

$$\frac{dC_q}{dC_0} = -f'(K_{q-1} - C_{q-1})f'(K_{q-2} - C_{q-2}) \dots f'(K_0 - C_0) = -\frac{\partial T(\cdot)}{\partial C_0} \div \frac{\partial T(\cdot)}{\partial C_q}.$$

The reciprocal of this product (in absolute value) is the "price" in terms of C_0 of producing an additional unit of C_t ($t=q$). The latter "price" is in a sense the counterpart of the price P_t which we considered in Section I. Similarly $f'(K_t - C_t) - 1$ is the counterpart of r_{t+1} .

The problem which we must investigate now is whether it is possible in the present model to determine the optimal values of C_0 and of capital accumulation by means of a two-dimensional utility analysis, where one variable is C_0 and the other variable is an index of future consumption possibilities. We shall now show that the answer to this question is positive. We shall also show how the reduced utility function is to be constructed from the original (complete) one.

Consider first the case $n=3$ described by (6). Note here that C_0 and K_0 enter $T(C_0, C_1, C_2, C_3; K_0)=0$ by means of the expression $f(K_0 - C_0)$. However, since the latter equals K_1 , we may write (6) as

$$C_3 - f[f(K_1 - C_1) - C_2] \equiv T^*(K_1, C_1, C_2, C_3) = 0$$

which defines a transformation function between K_1, C_1, C_2 and C_3 . In general this function is $T^*(K_1, C_1, \dots, C_n)=0$. Now the maximization problem when we work with the complete system is: maximize

$$U(C_0, C_1, \dots, C_n) \quad \text{w.r.t.} \quad C_0, C_1, \dots, C_n$$

subject to the production constraint $T(C_0, C_1, \dots, C_n; K_0)=0$. Let us break this problem down into two stages. In the first stage maximize $U(C_0, C_1, \dots, C_n)$ subject to $T^*(K_1, C_1, \dots, C_n)=0$ for arbitrary values of C_0 and K_1 . Now for given arbitrary values of C_0 and K_1 it is possible to determine an optimal set of C_1, \dots, C_n which (together with C_0) corresponds to a particular value of U (). This (conditionally) maximized value of U , to be denoted by Um , will of course vary for alternative sets of (C_0, K_1) . Let us denote the dependence of Um on C_0 and K_1 by a function, say $Um=M(C_0, K_1)$.¹¹ Given any pair of collections (C_0, K_1) , the consumer can determine directly by means of $M(C_0, K_1)$ which one he prefers. Hence $M(C_0, K_1)$ may serve the same analytic purposes as an ordinary utility function in the two-commodity case.

While the utility function is defined for arbitrary values of C_0 and K_1 , it is clear that from the point of view of the production possibilities these variables are not independent. In fact, by (4), these variables are related by means of the transformation function $K_1 - f(K_0 - C_0)=0$. In order to determine the optimal values of C_0 and K_1 , we must therefore go

¹¹ Alternatively, the optimal values of C_1, \dots, C_n which correspond to every set C_0, K_1 can be expressed by means of functions, say $C_t = g^{(t)}(C_0, K_1)$. Substituting these functions in U we obtain

$$U[C_0, g^{(1)}(C_0, K_1), \dots, g^{(n)}(C_0, K_1)] = M(C_0, K_1).$$

through a second stage of maximization where we maximize $M(C_0, K_1)$ subject to $K_1 - f(K_0 - C_0) = 0$. We may now regard the second stage of maximization as the standard (two-period) problem of maximizing a utility function $M(C_0, K_1)$ subject to a production (or budget) constraint. This establishes the fact that in the present model K_1 can fully represent future consumption plans.

The equilibrium position is illustrated by the point E in Figure 1. The slope of the transformation curve at this point, i.e., $f'(K_0 - C_0)$, is the marginal rate of transformation between C_0 and C_1 . This rate (minus 1) is also the relevant marginal rate of return on investment. The size of capital accumulation can be calculated by $K_1 - K_0$. Finally note that by varying the initial amount of K_0 we can trace out the whole income consumption curve RR' from which we may derive the consumption function $C_0 = C(K_0)$. This is the demand function for C_0 in the present model since K_0 is the only exogenous factor.

We may note that K_1 , which is "planned wealth for the next period," is the variable which Dewey uses in his two-dimensional analysis. It is easy to see that the foregoing analysis can be carried out alternatively in terms of Leontief's "perpetual consumption" measure. The constant value of future consumption, say C_f , can be obtained by solving the equation $K_1 = f(K_1 - C_f)$ for C_f . Thus if $C_1 = C_f$, then $K_2 = K_1$ so that C_f can be maintained forever. We now assume that $f'(K_1 - C_f) > 1$ for all values of K_1 , i.e., at $K_1 - C_f$ the marginal *net* rate of return is positive (note that if there are no transfer costs between periods then f' can never fall below unity¹²). Under this assumption C_f is a monotonic increasing function of K_1 , so that we may also express K_1 as a function of C_f , say $K_1 = g(C_f)$. Substituting $g(C_f)$ for K_1 in the utility function M we obtain $M[C_0, g(C_f)] \equiv M^*(C_0, C_f)$. Similarly substituting in the production function we obtain $g(C_f) - f(K_0 - C_0) = 0$. It can be verified by differentiating the latter transformation function w.r.t. C_0 and C_f , using the assumptions $f' > 1$ and $f'' < 0$, that it is of the usual type (i.e., negatively sloped¹³ and concave). We now have a utility function and a production (or transformation) function in terms of C_0 and C_f , so that we may carry out the two-dimensional utility analysis in the usual manner.

It may be noted that at alternative equilibrium situations (corresponding to alternative values of K_0) the MRT's between C_0 and C_1 will generally vary. It seems therefore somewhat surprising that in spite of this fact the two-dimensional analysis (as in Fig. 1) remains valid whereas the aggregation procedure in Section I failed when we varied

¹² This has been pointed out to me by D. Patinkin.

¹³ More specifically

$$\frac{dC_f}{dC_0} = - \frac{f'(K_0 - C_0)}{f'(K_1 - C_f)} [f'(K_1 - C_f) - 1].$$

FIGURE 1

interest rates (and hence the transformation rates). The explanation is however simple and is related to the fact that in Section I the interest rates were *exogenous* and the corresponding P_t 's were given parameters from the point of view of the consumer. Consequently when the P_t 's changed in different proportions, we could argue by means of the Hicksian composite good theorem that the aggregation procedure is generally not valid. In the Robinson Crusoe model, however, the transformation rates are *endogenous* and cannot therefore be interpreted as exogenous prices. The only parameter which varies in the latter model is K_0 , and this corresponds exactly to a change in initial wealth W , in Section I, with the r_t 's remaining constant. It may be recalled that in this case we *could* define in Section I a true composite good to represent future consumption. The general result is therefore that, when we deal with "wealth effects" (of changes in W or K_0), we can always define a meaningful composite good of future multiperiod consumption.

One may introduce into the Robinson Crusoe economy something similar to *exogenous* interest rates by assuming some form of (expected) technical change. Suppose, e.g., that instead of (3) we have $K_{t+1} = bf(K_t - C_t)$ where $b(>1)$ is a parameter of technical change which is known to Mr. Crusoe. On the basis of this production function we may derive a utility function $M(C_0, K_1)$ as before. However as the (exogenous) b changes, the former indifference map will no longer be valid.

A similar statement can be made concerning the labor input which we have assumed to be constant. Suppose that in each period there is a certain quantity of exogenously given labor input. If this quantity varies among periods, then for each period we shall have a different production function, say $K_{t+1} = f^{(t)}(K_t - C_t)$. This does not prevent us from deriving a utility function $M(C_0, K_1)$ as before. However, the latter function will depend on the parameters of labor input. For an alternative set of labor inputs the original $M(\)$ becomes meaningless.

III. Conclusions

For an individual consumer, who is faced with exogenous interest rates, it is possible to perform perfect aggregation over the stream of future consumption in order to carry out a two dimensional analysis of *current* consumption and of *current* capital accumulation under the following conditions: (a) When the interest rates are fixed throughout. In this case we can study the effect of a change in wealth on the foregoing variables. (b) When all interest rates are fixed except the one between the current period and the next one (r_1). In this case we may study, in addition to the effect of a change in wealth, the effect of a change in r_1 . (c) When the utility function is restricted to the special form

$$U[C_0, H(C_1, \dots, C_n)]$$

where $H(\)$ is a homogeneous function. It is then formally possible to describe the consumer's equilibrium in terms of C_0 and the value of H by means of a two-dimensional indifference-curves diagram. In this case, however, the two-dimensional analysis is of limited use since the slope of the budget line will depend not only on interest rates but also on the consumer's tastes, i.e. on the specific form of the function $H(\)$.

When we extend our analysis to deal with the economy as a whole the interest rates become endogenous variables and consequently our analysis must be confined to the effect of changes in initial capital. In particular for a Robinson Crusoe economy with a single homogeneous good and a simple Ramsey-type production function $K_{t+1} = f(K_t - C_t)$ it is possible to carry out a two-dimensional utility analysis of K_1 and C_0 for the purpose of studying the effects of a change in initial wealth [as in case (a) above].

The Role of Capital-Goods Trade in the Theory of International Trade

In most treatises on the theory of international trade, the causes and nature of trade in capital goods receive little attention.¹ Typically, only when international movements of capital funds are introduced into the discussion is such trade even mentioned and then usually only in connection with the so-called "transfer" problem. Trade models that follow the traditional assumption of excluding international movements of capital funds invariably are set up entirely in static terms. A given stock of capital equipment is assumed to exist, and the possibility of any net saving is ruled out. Consequently, an exchange of currently produced consumption goods for part of a country's given stock of capital goods is not possible, since it would involve domestic saving by the nation importing the capital goods.²

This traditional approach is completely inadequate in these times, when economic growth is such an important goal, especially for the less developed nations. Capital-goods trade is a crucial part of the dynamic relationship between international trade and development. Part of the imports of investment goods into less developed countries is financed by international flows of capital funds, but a significant portion of this trade is financed by current foreign exchange earnings. International trade theory must cover both situations. The production of capital goods as well as consumer goods must be introduced into trade models, and the entire analysis integrated with domestic capital accumulation theory.

This paper will modify the static nature of existing trade theory by introducing explicitly the possibility of capital-goods trade that is financed from current export earnings. The factors that determine whether in fact at a particular time such trade will take place and, if so, how much and at what exchange ratio are analyzed as well as the elements affecting changes in the volume and terms of this trade as accumulation and growth proceed. Similarly,

¹ In his survey article on trade theory, J. Bhagwati comments upon the lack of analysis on this subject and also surveys what recent writings there are on the topic [1, pp. 51-53]. However, since Bhagwati's paper appeared (and also since this paper was written), H. Oniki and H. Uzawa have published an elegant mathematical analysis of trade in capital goods [9]. In contrast to the comparative statics approach here, Oniki and Uzawa frame their analysis in dynamic terms. The main difference in basic assumptions is that they postulate a constant average propensity to save throughout the accumulation process, whereas savings is made a function both of the interest rate and the level of income in the model used here.

² It is perhaps not out of place to remind ourselves that the traditional assumption of trade theory concerning the immobility of capital refers to abstract capital and not capital goods. See, for example [8, p. 77] [2, pp. 5-6] [3, p. 27].

Another method commonly followed to avoid the issue of capital-goods trade is to assume that labor and natural resources are the only productive factors. [7] and [4] are examples of writers using this approach.

the impact of capital-goods trade on the development process itself is analyzed. The case where capital funds as well as capital goods flow across international borders also is included and contrasted with the situation where only capital-goods trade occurs.

I

For explanatory purposes, it is useful first to consider the pattern of accumulation within a country in the absence of both trade in capital goods and international capital movements. Suppose there are two commodities, one of which is an infinitely durable capital good that, together with the other factor, labor, can be employed in producing either additional units of this capital good or the other consumption commodity. The actual quantity of the capital good produced in any time period is a function of the preferences of the population for the consumption good over their time horizons and the technological nature of the production functions for the two commodities.³ In a world of perfect certainty in which future markets exist, a particular time pattern of investment would be selected by the community at the outset and followed during the entire accumulation process. However, if there is imperfect knowledge about the future, individuals will revise their accumulation plans as time passes and new information becomes available.

A simple model based upon the latter type of behavior, which was developed by Leontief [5] [6] [12], is represented in Figure 1. The indifference curves in the first quadrant, e.g., i and i' , show the community's preferences between present and future consumption.⁴ In selecting the current period's saving level, decision units in the economy are assumed to act as if they will not accumulate additional capital in any future periods. However, as each period passes, they revise these plans and undertake further saving until the marginal productivity of capital falls to the level at which it equals the community's marginal time preference rate between present and future consumption at the current period's income level.

The fourth quadrant indicates the current period's production-possibility curve between the consumption commodity and the capital good. This curve shifts outward over time as the productivity of the given labor force is raised by means of capital accumulation. The third quadrant shows the increase in potential consumption associated with the various quantities of the capital good that can be produced in the current period. This consumption-output curve for various sizes of the capital stock (and the full utilization of the fixed

³ In the model and throughout this paper, production functions are assumed to be homogeneous of the first degree and to be identical for all trading partners. Factor-intensity reversals are also ruled out. In addition, it is assumed that there are no qualitative differences between the labor forces of different countries.

⁴ Since this paper is not concerned with the welfare aspects of international trade, it is useful for expositional purposes to assume that each individual in a country is identical with respect to tastes and factor endowment. For simplicity, the community's preference for present versus future consumption also is taken to be such that at a given interest rate the fraction of income saved remains constant as income increases. However, the higher the interest rate, the higher this fraction becomes.

labor supply) is drawn such that in each period it begins on the x -axis at a point indicating the maximum amount of the consumption good that the economy can produce in the period. For example, initially it is supposed that OA (equals OG) of the consumption good can be produced if all available capital and labor are used for this purpose. If, however, AB of current potential consumption is foregone in order to produce BC of the capital good, potential consumption in future periods will increase by GI . To represent this possibility in the first quadrant, as well as all the other possibilities between present and future consumption (the curve RTL), a 45° line is drawn in the second quadrant from I to J . Thus if the economy saves RS (equals AB) of current income and accumulates BC (equals IH) of the capital good, it will be left with OB of the consumption good in the current period, but can produce BT (equals OI and OJ) of this commodity in each future period.

FIGURE 1

Since an indifference curve between present and future income is assumed to be tangent to the consumption-possibility curve between present and future periods at the point T , the community will save RS in the initial period.

On the basis of the capital accumulated in the first period, the production-possibility curve shifts outward to te . The capital-output curve beyond the point H is also redrawn beginning at OI (equals Ot) in order to depict the output possibilities associated with further accumulation. From these two curves a new consumption-possibility curve could be drawn in the first quadrant, and a new saving point determined. The consumption-possibility curves will eventually become flatter over time as the marginal productivity of capital declines. When an indifference curve is tangent to a consumption-possibility curve at a point on the 45° line, a stationary-state position is attained.⁵

II

Consider now the effects on this accumulation process if international trade in the two commodities is opened up. Should the country be able to trade all of its potential output of either good (as well as the stock of capital goods already produced) at an exchange ratio indicated by the slope of the line abc , its consumption-possibility curve would shift outwards to $hfvK$.⁶ Compared to the former consumption curve (RTL), this new consumption-possibility curve permits the community to select a point at which both current and future consumption will be greater than previously. Assuming the point v to be the optimum point, the economy accumulates nm of capital in the period, partly by domestic capital-good production and partly by exporting the consumption commodity for additional amounts of the capital good.

For each hypothetical exchange ratio there will be a new consumption-possibility curve, a particular optimum volume of capital accumulation, and an international offer of one commodity for the other. The actual exchange ratio and trade that will emerge in the period depends upon the shape of the offer curves of all the trading nations and is set at the point where total exports equal total imports for each of the two items.

Unless countervailing saving preferences offset the production biases, a relatively capital-scarce nation will import the capital good, which is assumed to be uniformly capital-intensive compared to the consumption good, and export the consumption commodity. The effect of this trade will be to accelerate capital formation in countries importing the capital good, compared to the growth that will take place from a given initial factor endowment level in the non-trading case. However, the accumulation rate may or may not increase for the capital-good-exporting nation.⁷

⁵ One could introduce given rates of population growth and technological progress so that the system approached some positive growth rate rather than a stationary position.

⁶ The fh portion of the curve is based upon the exchange of the existing capital stock for the consumption good at the given exchange ratio.

⁷ This point can be shown in Figure 1. Since the price of capital goods falls for this capital-good-importing country after trade is opened up, the new consumption-possibility

As explained in the no-trade case, capital formation pushes out a country's production-possibility curve. This output expansion will be accompanied by a gradual decline in the relative price of the capital good.⁸ The interest rate will also decline as the marginal productivity of capital falls. Moreover, since the decision units in each economy revise their investment plans each period as their incomes rise and in fact continue to save as long as the expected marginal productivity of capital is greater than their marginal time-preference rate between present and future income, actual interest rates (as distinct from expected rates) will be equal among those trading nations who produce some of each commodity.⁹ The interest rate will finally decline to a level where no further saving takes place.¹⁰ If tastes are the same among the trading nations, a group equilibrium position will be reached with each nation possessing the same capital/labor ratio.¹¹ Trade in the two commodities will cease at this point.¹²

Shifts in the terms of trade for countries either exporting or importing capital goods are affected by much the same sort of factors determining the exchange ratio for countries trading consumption goods. For example, a shift in preferences that raises saving propensities in either group of nations works to worsen the terms of trade of the countries importing capital equipment. Increasing the initial stock of capital in either group of countries or raising the marginal productivity of capital, however, may either increase or decrease the price of capital goods, depending upon the relative strength of the substitution

curve directly east of the old equilibrium point T, must be steeper than at T. Therefore, if future consumption is not an inferior commodity, the total volume of capital goods imported and produced domestically will be greater than under the no-trading conditions. For the capital-good-exporting nation, however, the new consumption-possibility curve will be flatter than before directly east of the old equilibrium saving point. Consequently, a lower accumulation point could be chosen without violating the noninferior good assumption.

If the assumption of similar tastes and factor endowments for all individuals within each country is dropped, these conclusions will be modified. In particular, since—under the usual assumptions about production functions—the opening-up of trade increases the income of the abundant factor and decreases that of the scarce factor, there is likely to be a redistributive effect that lowers the aggregate saving propensity in labor-abundant countries and raises it in capital-abundant economies. It is possible for this shift to be so strong that initially the growth rate declines in labor-abundant countries that import capital goods.

⁸ This follows from the export-creating effect of capital accumulation for countries exporting the capital good (and the import-replacing effect of accumulation for countries importing the capital good), i.e., the Rybczynski effect in production, and from the assumption of a positive marginal propensity to consume the consumption item in the future periods.

⁹ Besides the production of some amounts of the capital good and the consumption good, this condition requires that the full set of other assumptions needed for factor-price equalization be satisfied. See [4, pp. 48-49] and [10].

¹⁰ A country might still export capital goods at this stage, however.

¹¹ If tastes differ among the trading countries, relative factor endowments will not be the same at a no-trade, stationary-state equilibrium point. World income also will be higher than under no-trade conditions.

¹² The rate of interest, however, will still be equal among the countries, even though there is no production of the capital good.

and income effects between present and future consumption. The same holds true for increases in the labor supply, except that in this case the factor increase—besides having a production effect—tends to decrease a country's propensity to save and therefore its demand for capital goods.

Should the relatively capital-abundant nations impose tariffs on the export product of the capital-scarce areas and thereby lower the international price of this item relative to the capital good, the accumulation rate of the latter nations will slacken. On the other hand, if the capital-scarce nations possess and exercise their monopoly power without retaliatory action by the capital abundant areas, they will increase their capital-formation rate.

III

Consider next the effects of dropping the assumption that capital is immobile between countries. This means that capital goods can flow from one country to another without being financed by consumption-goods exports. Under the assumptions made in elaborating the previous model, the opening-up of capital flows will result in a transfer of part of the capital stock of capital-abundant nations to the capital-scarce countries. The transfer will cease when all possess the same ratio of capital to labor, since at that point the marginal productivity of capital will be the same in every country. However, this is not the end of capital flows and trade even under the assumption of similar preferences¹³ in both trading nations. National income as distinct from domestic product will be higher in the creditor nations due to the interest payments on their invested capital. Whereas the consumption-possibility curves for domestic investment will be the same in all countries, the volume of savings will be greater in the creditor countries because of their higher income levels. Additional capital, therefore, will tend to flow into the initially capital-poor countries as the accumulation process runs its course. Furthermore, the capital goods needed to undertake this additional accumulation will not be entirely produced in the initially capital-rich countries. Since the production possibility curves are the same in all countries, it will be advantageous for the creditor countries to obtain some of the capital goods needed for their investment in the debtor nations by purchasing them with exports of the consumption commodity.

Under the similar taste assumption the equilibrium capital-labor ratio will be the same in this case as in the no-trade and capital-goods-trade cases. But, unless the equilibrium interest rate is zero, the income level of the initially capital-abundant nations will be higher than in the relatively capital-scarce countries, because of their interest receipts. The capital-scarce countries are, on the other hand, able to reach the equilibrium capital-labor ratio in a shorter period of time than in the trade-alone and no-trade cases. They reap the benefits of capital accumulation on the productivity of their labor without having to pay the full foregone-consumption price of the equilibrium capital stock.

¹³ Time preference functions are assumed to have the characteristics described in footnote 4.

IV

The preceding conclusion concerning the cessation of trade when equilibrium is reached has been based upon a simple two-commodity, two-factor model. Introducing another capital good as both an input and output does not change this conclusion. However, if the output bundle is composed of (say) two consumption goods and one capital good and the factors of production consist of the capital good, labor, and a natural resource, then the outcome is modified. With two immobile factors, the same factor ratios in general will not be reached among trading nations under the similar taste assumption, and trade in consumption goods will continue at the stationary-state position.¹⁴

For a larger proportion of trade, however, fixed natural resources (as distinct from traded primary products) are likely to become a less important source of comparative cost differences among countries as technology and living standards rise in the world. It may be increasingly useful to regard international trade, especially among the more advanced countries, as essentially an adjustment process in response to a disequilibrium situation. Moreover, if we consider the skill component of the labor force as a manipulatable variable that, by means of educational expenditures, changes during the capital accumulation process, then factor-ratio differences other than those based on natural resources are not permanent. Therefore, trade should be regarded as based on such factors as short-run differences in the knowledge of productive techniques, and differences in tastes—a factor that may also be best regarded as short-run. Differences in the nature and rate of technological discoveries, differences in rates of population growth, differences in preference changes, etc., may well maintain the relative importance of international trade, but the pure theory of trade should make clear the dynamic forces tending to reduce trade. By ignoring capital-goods trade that is financed by current exports, international trade theory has failed to do so.

Foreign Graduate Students in Economics

Since the end of World War II there has been sustained growth in the number of foreigners undertaking graduate work at U.S. universities. For the last ten years the rate of increase has averaged 11 per cent per year,¹ considerably higher than the average 7 per cent rate of growth² in total graduate enrollment. Behind the expansion lies a complex of factors: a world-wide emphasis on education and development which has resulted in a rise in the demand for trained personnel; a willingness on the part of U.S. graduate schools to accept for training a large number of students from abroad; the ability of institutions to provide the necessary financing; and an improvement in education in many countries which has prepared more students for graduate work. Foreign students inevitably raise problems for the universities. While the problems are not different in kind, they are certainly exaggerated in degree from those associated with training Americans. It is harder to interpret and compare credentials of foreign applicants; to find adequate financing for foreign students who are frequently unable to draw upon personal funds because of currency regulations, and whose employment opportunities in the United States are restricted by law; to design courses with content and level appropriate for students of diverse backgrounds; to teach people whose comprehension of English is imperfect; and to find topics suitable and faculty able to supervise dissertations for those who wish to work on problems of their own countries.

As recently as a decade ago these difficulties, at least as regards departments of economics, were largely confined to a small group of universities

¹ This is the rate of growth for the decade 1954-1964. Each year the Institute of International Education conducts a census of foreign students in the United States. The figures on overseas students are taken from the Institute's annual reports [4].

² This rate is for the nine years 1954-63. The figure on graduate enrollment for 1963 was taken from [7], that for 1954 from [6, p. 210].

which trained the majority of students from abroad.³ But today graduate students from overseas are found in almost all U.S. economics departments.⁴ The problems, especially those of selection, are compounded by the fact that applications no longer come from a select group of overseas schools but from a wide array of countries and institutions.⁵ The increase in graduate students from abroad in economics has averaged 20 per cent per year⁶ compared to 12 per cent⁷ for the total graduate enrollment in economics. Today with roughly one out of every four advanced students being foreign, economics is as a discipline second only to agriculture in the percentage of its graduate candidates who come from abroad.

While the number of graduate students in economics from all areas of the world has risen in recent years, the most rapid growth has been in students from Africa and Latin America. Table 1 shows the number of students coming from the world's principal regions and separately for countries with 35 or more graduate students in economics. Information is also given in the table on the country of origin of graduate students in business administration, all foreign students, and graduate students in economics for the year 1962-63.⁸

Some students from abroad never go back to their homelands. It has been estimated that in total about 10 per cent of all foreign students remain in the United States, but no more than 7 per cent of the Chinese students from Taiwan, Hong Kong, and other South East Asian countries ever return to that area of the world [3]. The percentage going back to Korea is not much larger. Other countries with a substantial "loss" of students include India, Iran, Egypt, Lebanon, Pakistan, Greece, Colombia, Argentina, and Ecuador [3]. No separate information is available for economists,⁹ but anyone who has visited the campuses of the smaller colleges is aware that a substantial number of

³ During the decade 1945-54 over half the foreign graduate students in economics were trained at 10 institutions.

⁴ There is still considerable concentration of foreign students at particular schools; half the foreign economics students were enrolled at 18 institutions in 1964-65. But out of 170 universities offering graduate work in economics, 153 reported at least one foreigner enrolled.

⁵ In 1964-65 graduate students in economics came from 109 countries. During the decade 1945-54, 40 per cent of foreign students in economics came from European and North American universities; in 1964-65 only 20 per cent came from these two areas.

⁶ The data on students in economics are available only for recent years. The rate reported is for the three-year period 1961-64 and is based on special tabulations prepared by the Institute of International Education.

⁷ This rate is for the three-year period 1960-63 and is taken from the annual reports of [7].

⁸ These figures exaggerate the numbers coming annually from India, China, Korea, and the United Arab Republic. Of those who began their graduate work in economics in 1963 or 1964, only 4.7 per cent came from India, 6.4 per cent from China, 3.2 per cent from Korea, and a 1.4 per cent from the United Arab Republic. The difference in figures is due to the fact that students from these countries remain longer on average in the United States.

⁹ Herbert Grubel has provided the author with some unpublished data on the number of foreign-born economists in the United States. His figures show that 1300 or 12 per cent of the total are foreign born. Of this number, however, only about 300 came from regions other than Europe and Canada.

faculty at these schools are foreign-born. The new immigration bill will probably increase the number of those remaining in the United States by granting immigrant status to individuals "capable of performing specified functions for which a shortage of employable and willing persons exists in the United States..." [8, p. 7].

Table 2 gives information supplied by economics departments with 30 more students from abroad on enrollment, degrees, and financing of foreign graduates.¹⁰ Eight of these 18 departments appear on Cartter's list of the country's leading 20 [1]. In fact, of all foreign graduate students in economics in 1964-65, 40 per cent were enrolled at the leading 20 institutions.

Officials of the leading departments reported to the author that in the past the mean academic performance of foreign graduate students in economics has been poorer than that of U.S. students, and the dispersion of the foreign records has also been greater. Table 3 gives a breakdown on enrollment and degrees for 98 departments of economics as a group, and for 18 departments of agricultural economics. This information suggests that, at least in regard to earning degrees, foreigners do about as well in graduate schools as domestic students. For example while 27 per cent of the present Master's candidates are from abroad, foreigners received 30 per cent of the Master's degrees between 1959 and 1964. For doctoral candidates the situation is that 25 per cent of the students are foreign and between 1959 and 1964 foreigners received 20 per cent of the degrees. In the past, however, the proportion of doctoral candidates from overseas was smaller than it is today; adjustment for the lag would show that foreigners have also been about as successful as Americans in earning the Ph.D. degree.¹¹

The data in Table 2 suggest that at some schools foreigners have been less successful than Americans in earning the doctorate. A comparison of enrollment and degrees is, however, less accurate for a single institution than for a group. At the 20 leading departments 28 per cent of the enrolled doctoral candidates are foreign; between 1959 and 1964 students from abroad earned 20 per cent of the Ph. D.'s awarded by these departments.

The tabulations of the Institute of International Education show that the percentage of foreign graduate students studying for the doctorate in econo-

¹⁰ The departmental figures used in this communication are, except where noted, drawn from reports submitted by the departments to the AEA for the compilation of [5]. Though all figures were checked with the departments, the author feels that certain questions may have been misunderstood and the figures inaccurately reported by some departments.

¹¹ It has been said that some departments do not require as high a level of performance from foreign students as from Americans for the degree. Wharton [9] [10] stresses this point and then, as have other commentators on the subject, condemns the awarding of "second class" degrees to those from abroad. Wharton's policy prescription is to ask foreigners to achieve the same level of attainment by spending longer on their education. There may, however, be a role to be played by "half-trained" economists; using Friedman's analogy in discussing the training of doctors and lawyers [2, p. 153], the developing countries probably cannot afford only "Cadillac" economists. Certainly some American colleges employ teachers without the highest level of training. Perhaps the policy solution is more "labeling" rather than more training.

^c For a few departments the period for which degrees were reported differed slightly from the dates indicated, e.g., 1960-64.

ics rose from 30 per cent in 1962 to 40 per cent in 1964.¹² This trend seems destined to continue. Universities in the developing world are now attempting to upgrade standards by employing better-trained faculty. In the future most of those seeking Master's degrees will probably be planning careers in administration.¹³ And many of these will receive their training in their own or neighboring countries. For these reasons it seems unlikely that there will be much growth in the number of foreigners seeking the M.A. degree in the United States. On the other hand, an increase in the number of applicants for doctoral programs seems almost certain because of the expansion in the foreign demand for people with the Ph.D. and in the supply of those prepared to undertake graduate work at an advanced level.

Table 4 shows that in 1964-65 only a fraction of foreign students received all or part of their funds from the universities. Universities tend to award their own funds to doctoral candidates, students from developed countries, and those already on campus. Other institutions giving aid follow different policies. The United States Government, for example, emphasizes fellowships of one or two years for Master's candidates from developing areas. Graduates in economics get considerably more support from their own and the United States government than do students in general; the governments of the Near East and Africa are particularly active in supporting economists.

¹² The departmental figures presented in Table 3 indicate that 50 per cent of the foreign students were pursuing doctoral programs; the difference is explained by the fact that most of the departments not included in the table offered only Master's programs.

¹³ For these students graduate schools of business and public administration may provide training more suitable to their career objectives than departments of economics.

* Based on special tabulations prepared by the Institute of International Education and tables in [4]. Those who were financed by two sources (e.g., university and United States Government) are divided equally between the two classes.

Foreign students may well find it increasingly difficult to win acceptance at the leading institutions. Seven out of the top 20 departments (as listed by Cartter [1]) no longer offer programs leading to the Master's degree. And because their preparation is different, foreign candidates frequently require semi-remedial training before beginning their doctoral studies; at institutions without a Master's program, courses at this level are commonly not available. The seven departments specializing in doctoral work follow restrictive admission policies, accepting in 1964-1965 on average only 13 per cent of their foreign applicants against a 43 per cent acceptance rate at the other 13 leading departments. If specialization spreads, there may be a demand in the future for some departments to offer a Master's program designed to prepare students with weaker backgrounds, both foreign and American, for doctoral work at the leading institutions.

To assist the economics departments determine which applicants meet their admission standards, the AEA has established a Foreign Students Screening Project. Committees of economists have been set up in many developing countries to interview candidates, evaluate their credentials, and report to the economics departments on student qualifications. Any department wishing an

evaluation of a foreign applicant should contact the Association's offices in Evanston. At least six weeks time should be allowed to obtain a report.

An Implication of the Labor-Surplus Assumption

In recent articles, G. Ranis and J. C. H. Fei [1] [3] have significantly elaborated the basic W. A. Lewis model [2] of the labor-surplus economy. In their model, a successful development effort is fueled by the saving of industrial capitalists which permits a portion of industrial output to be invested in both the industrial commercialized sector and the agricultural labor-surplus sector. Investment must be allocated to permit the simultaneous absorption by the industrial sector of (1) a larger agricultural surplus, and (2) a greater proportion of the labor force (at a constant real wage) [3, pp. 540-46].

Since the allocation of investment between the two sectors is crucial to the growth and labor reallocation process, more should be said about the capital-allocation mechanism than the authors have already done [3, p. 545]. This brief note suggests that the micro foundations of the agricultural sector's private investment function may be extremely shaky so long as

labor-surplus conditions prevail. Official intervention in investment decisions may indeed be in order, as the authors suggest [3, p. 545], if the development effort is to succeed.

The labor-surplus assumption implies that the marginal social product of capital (its shadow price) exceeds its marginal private product. Moreover, an exogenous rise in the labor force (e.g., due to higher birth or survival rates) will drive down the private return to capital while its social product rises. Conversely, an increase in capital employed with a given labor force will raise its private return although its marginal social product falls.

This "perverse" effect is illustrated in Figure 1. The capital stock and land are held constant, and labor is plotted along the horizontal axis. The marginal products of labor (f_L) and capital (f_K) are plotted along the vertical axis together with the traditional real wage (\bar{u}) and the private return to capital (r). Labor surplus conditions prevail if L exceeds L_0 , since the marginal product of labor falls short of its real wage in that range. At L_0 , the total product is

$$\sum_0^{L_0} f_L \Delta L.$$

The wage bill is $OL_0H\bar{u}$ and capital's rent is the shaded "triangle," E . The marginal private and social rates of return on capital coincide at $r_0 = f_{K0}$. If the labor supply were to rise to L_1 , the wage bill rises to $OL_1D\bar{u}$, and capital's rent is reduced by the shaded triangle, F . The marginal social return on capital rises to f_{K1} but its marginal private return falls to r_1 .

It would be hazardous to ascribe economic meaning to these results without detailed knowledge of the micro decision-making units and their institutional environment. The crucial point is whether or not investment decisions are made with respect to the marginal social product of capital (f_K) or its

FIGURE 1

marginal private product (r). If investment decisions are made within an extended family unit, then little if any distinction is made between capital and labor income. Consequently, this type of unit can be expected to compare the change to its total product by adding more capital with the marginal cost of doing so. Thus f_K , not r , is the relevant decision-making variable, and no special problem is introduced by the divergence of f_K and r owing to labor-surplus conditions.

On the other hand, if the investment decision is made by a landlord who (1) has alternate investment opportunities, (2) is committed to paying the traditional real wage, and (3) is unwilling or unable to control L , then r is clearly relevant, not f_K . If r_0 is the opportunity cost of investing in his agricultural enterprise, then a rise in labor from L_0 to L_1 may induce him to allow his agricultural capital to depreciate and invest elsewhere. Alternatively, he may raise his rate of return by more investment, restoring r to r_0 . But surely it is not clear that a falling rate of return will induce a higher rate of investment.

Various tenant and sharecropping arrangements bring both f_K and r into a joint decision-making process too involved to analyze here. Nevertheless, perhaps enough has been said to suggest that the labor-surplus assumption may imply private investment behavior in the labor-surplus sector which could lead to underinvestment in agriculture, a fall in the industrial terms of trade with agriculture, and a consequent retardation of the development process.

Some Simple Propositions Concerning Cost-Push Inflation

The government's wage-price guidepost policy is predicated on the assumption that firms in basic industries possess discretionary pricing power. But this assumption in itself does not suffice to justify government intervention in steel, copper, and aluminum pricing decisions. The case for intervention rests on the presumption that price adjustments in those key sectors have a significant effect upon the general price level. Clearly, if wage-price guideposts are to be frequently invoked in an attempt to combat infla-

tion, the task of obtaining quantitative estimates of the inflationary impact of autonomous price and wage adjustments in key sectors of the economy is of critical importance.

How much inflation would have been generated if the price of steel had increased by \$6.00 per ton in 1962? Obviously, the answer to this question must hinge in large measure upon the response of wages, profit markups, and prices in other sectors of the economy. In the first section of this paper we estimate the extent of the inflation that would have been generated if the price of steel had increased by \$6.00 per ton in 1962 while the response of other sectors of the economy was constrained by the guideposts. Guidepost policy allows steel-using firms to respond to rising material costs by raising their prices rather than reducing their profit margins; similarly, the customers of steel-using firms may pass along their costs, and so on to the eventual consumer. On the other hand, the guide posts do not permit money wage rates to adjust in response to rising prices.¹ If the price response of steel-using sectors and labor are not governed by the guideposts, our initial estimate of the inflationary effect of a \$6.00 increase in the price of steel must be modified. Section II considers the implications of certain sectors absorbing cost increases from profit margins rather than passing them along to their customers. Section III evaluates the effects of induced markup and wage increases that violate the guideposts.

Our estimates are based on a series of quite general propositions that can be employed for estimating the inflationary effects of autonomous price and wage adjustments in any sector. In deriving these propositions, we employ the input-output approach developed by Wassily Leontief [2] for analyzing price movements. This approach takes into account both the direct purchases of steel and the steel content of other purchased inputs in evaluating the effect of a change in the price of steel upon production costs in other industries. This same procedure was utilized by Otto Eckstein and Gary Fromm [1] in their analysis of the contribution of steel to the inflation of the 1950's. In contrast to Eckstein and Fromm, however, we shall employ the implicit GNP price deflator as a gauge of movements in the general price level. The complicated input-output procedure reduces to a matter of quite simple computations once the GNP deflator rather than the wholesale price index is selected as the gauge of movements in the general price level.²

¹ Wage increases under the guideposts are equal to the trend rate of over-all productivity increase, which can be regarded as exogenous in analyzing the incremental effects of autonomous price adjustments. On the other hand, firms are permitted to raise prices in response to increases in nonlabor costs. Cf. [5, p. 189].

² A disadvantage of the wholesale price index as a measure of inflation arises from the excessive weighting that it gives to such commodities as steel, because commodities enter the index repeatedly at successive stages of the production process. The GNP deflator has considerably broader coverage, including services and construction. While the GNP index has limitations as a measure of long-run price movements because of difficulties involved in making appropriate adjustment for quality improvements, this limitation is not critical when the objective is to measure the incremental effect on the general level of prices of autonomous price and markup changes. An advantage of the GNP deflator is that it is based upon current quantity weights.

I. The Basic Proposition

We shall establish the following proposition:

The impact upon the GNP implicit price deflator of an autonomous increase in the gross profit margin of a particular industry may be approximated by dividing GNP into the product of the change in the margin times the level of gross output for that industry, provided that gross profit margins in other sectors and wage rates are unaffected.

his proposition suggests that if the steel industry had raised prices by \$6.00 per ton in 1962 (an increase of approximately 3.8 per cent), it would have raised the general price level as measured by the GNP deflator by only one-tenth of one per cent;³ that is, since 98.3 million tons of steel were produced in that year and GNP was \$553.9 billion,

$$\frac{\Delta p}{p} = \frac{\$6.00 \times 98.3 \text{ million tons}}{\$553.9 \text{ billion}} = 0.001065 \text{ or } 0.1065\%.$$

Although this figure may appear small, there are several reasons why it probably overstates the inflation that would be generated by a rise in the price of steel if firms in other sectors of the economy and labor abided by the guideposts. We shall see that the derivation of our basic proposition requires the assumption that the composition of final demand and the input-output coefficients are insensitive to moderate changes in relative prices. In utilizing the final bill of goods that was actually purchased in the absence of the steel price rise in this calculation we are in effect employing a Laspeyres price index, and thus exaggerating the effects of the price increase.⁴ The assumption of fixed technological coefficients also contributes to an overstatement of the inflationary impact of an increase in the price of steel.⁵ Furthermore, the proposition refers to a gross profit margin rather than to a price increase; consequently, it leads to an overstatement of the effects of a \$6.00 per ton increase in the *price* of steel to the extent that the price adjustments permitted of other sectors under the guideposts, by increasing the

³ This is an estimate of the *incremental* effect upon the general level of prices of an increase in the steel margin. The actual change hinges upon how a host of inflationary and deflationary forces balance out. The implicit price index increased from 115.8 to 116.7 (1954=100) from 1961 to 1962, and our estimate is that the index would have stood at 116.8 if the price of steel had increased by \$6.00 per ton in 1962.

⁴ The GNP deflator is a Paasche index; it uses current rather than base-period weights. But since the \$6.00 per ton increase was not maintained, our measure utilizes weights in the absence of the price change, and is Laspeyres in the sense in which the term is used by welfare economists. More technically, prices are weighted in the GNP deflator in accordance with the actual composition of final demand (the final bill of goods); if the price increase had been maintained, the application of our proposition would have yielded the change in a Paasche index because the weights would have reflected the shift in the composition of final demand induced by the price change.

⁵ A hypothetical example will illustrate the necessity of assuming fixed technological coefficients. If aluminum and steel were essentially perfect substitutes, and if relative prices were such that steel-users were on the borderline of indifference between using aluminum rather than steel, a \$6.00 per ton increase in the price of steel would precipitate the general substitution of aluminum for steel without any material impact upon the price of final product.

costs of raw materials in the production of steel, prevent a full \$6.00 per ton increase in the steel margin.

In demonstrating the validity of our proposition it is convenient to employ matrix algebra. Let $P = [p_i]$ denote the row vector of industry prices, $A = [a_{ij}]$ an input-output matrix of technological coefficients a_{ij} revealing the quantity of good i required to produce a unit of gross output of good j , $M = [m_i]$ a row vector of gross profit margins, $L = \text{diag}(l_i)$ a diagonal matrix of labor coefficients indicating the amount of labor of the i th type necessary to produce one unit of the i th commodity, and $W = [w_i]$ a row vector of industry wage rates.⁶ Then the matrix equation

$$(1) \quad M = P - PA - WL$$

defines the gross profit margin of each sector as the difference between price and unit material and labor costs. Thus, the gross profit margin includes capital consumption allowances and indirect business taxes. From this expression it is apparent that given industry markups, wages, and the matrices A and L , the vector of sector prices may be determined by calculating

$$(2) \quad P = (M + WL)(I - A)^{-1}.$$

The GNP deflator is obtained by dividing GNP in current dollars by the value of final outputs measured by prices in the base period. Let the column vector $Y = [y_i]$ denote the final bill of goods whose components reveal for each commodity i the sum of investment, consumption, government spending, and the excess of exports over imports. Provided that trade, construction, etc., have been included as sectors in addition to manufacturing, GNP is simply PY , and the GNP deflator may be denoted by:

$$(3) \quad p = PY/P^0Y,$$

where the superscript indicates, in general, that the variables refer to the base period. Utilizing (2) in conjunction with the fundamental equation of input-output analysis, $Y = (I - A)X$, yields:

$$(4) \quad PY = (M + WL)(I - A)^{-1}(I - A)X = (M + WL)X;$$

this states that GNP is identical to the sum of value added by each industry. Substituting (4) into (3) and differentiating with respect to m_i , the i th industry's profit margin, we have:

$$(5) \quad \frac{\partial p}{\partial m_i} = \frac{x_i}{P^0Y}.$$

⁶ Our basic proposition does not require the use of an estimated input-output matrix. This means that exogenous changes in the input-output and labor utilization coefficients as a result of such factors as technological change offer no difficulties, although we do require that the coefficients be insensitive to moderate changes in relative prices and wages. Note too that empirical considerations do not restrict the number of sectors, no problem of aggregation confronts us, and in principle we could regard quantities as measured in conventional physical units (e.g., tons of steel and hours of labor); alternatively, of course, the output of each sector can be measured in terms of prices in a base period, the units of measure being dollars, as is customary in empirical input-output applications.

Because the model is linear,

$$(6) \quad \Delta p = \frac{x_i \Delta m_i}{P^0 Y},$$

which is our basic proposition. As a convention, it is convenient to adopt as the base P^0 the level of prices that actually would have prevailed in the absence of the margin change, hence, $100\Delta p$ is the percentage increase in the GNP deflator generated by the increase in the profit margin.

It is interesting to contrast the simplicity of (6) with the computations undertaken by Eckstein and Fromm [1] in their input-output analysis of the inflation of the 1950's. While they also assume that wage rates and profit margins in other sectors of the economy are unaffected by steel-pricing policy, they employ the wholesale price index rather than the GNP deflator. With this approach they have, instead of our equation (4), the expression:

$$(7) \quad PQ^0 = (M + WL)(I - A)^{-1}Q^0,$$

where Q is a column vector of weights in the wholesale price index. The level of the index, then, is

$$(8) \quad p_w = \frac{PQ^0}{P^0Q^0} = \frac{(M + WL)(I - A)^{-1}Q^0}{P^0Q^0}$$

and

$$(9) \quad \Delta p_w = \frac{c_i Q^0}{P^0 Q^0} \Delta p_i,$$

where the vector c_i is the i th row of $(I - A)^{-1}$. The implementation of this approach requires a reconciliation of the wholesale price index classification with that of an empirically estimated input-output matrix of flow coefficients, the inversion of $I - A$, and computation of the inner product of the vector of price index weights times the steel row of $(I - A)^{-1}$. This approach, unlike ours, is sensitive to errors in measuring the input-output coefficients.⁷

Charles L. Schultze [4] has employed a national-income-accounting framework which facilitates the comparison of industry price and cost movements with changes in the GNP deflator. He has emphasized [4, pp. 19, 52] that his detailed tables presenting the contribution of various sectors of the economy to changes in the general price level for the 1947-57 period should be given an accounting rather than a "casual" interpretation. Since his tables are based on a formula equivalent to that stated in our basic pro-

⁷ Eckstein and Fromm argued that if it had not been for the "extraordinary behavior of steel" the wholesale price index would have risen by 14 rather than 23 points from 1947 to 1958. This does not imply, however, that the application of their procedure would yield an estimate of the inflationary effect of a \$6.00 increase in the price of steel in 1962 grossly different from ours. The \$6.00 increase that generated so much excitement in 1962 was much smaller in magnitude than the steel price increases that occurred in the decade examined by Eckstein and Fromm.

position, our analysis suggests that precisely the same assumptions as those specified in this paper and by Eckstein and Fromm would have to be satisfied before Schultze's calculations could be regarded as indicating the extent to which various sectors have caused inflation. Specifically, changes in profit margins and money wage rates must be exogenous and, in addition, the technological coefficients must be insensitive to moderate changes in relative prices.⁸

II. Cost Absorption

If, as is sometimes alleged, firms in certain sectors of the economy exercise discretionary pricing power rather than responding promptly to changing demand and cost conditions, it seems probable that these same firms may choose partially to absorb cost increases, at least temporarily, rather than pass them along to their customers through higher prices. In these circumstances, the inflationary impact of an increase in a basic industry's markup upon the general price level will be reduced or delayed. We shall show:

When some industries absorb cost increases, while the remaining industries preserve profit margins in the face of changing costs, the inflationary impact of an autonomous increase in the gross profit margin of a particular industry is governed by the proportion of that industry's total output not required, directly or indirectly, by the cost-absorbing industries.

To verify this assertion, which constitutes the price-dual of Paul Samuelson's application of the LeChatelier Principle to input-output models [3], let us suppose, as a matter of notational convenience, that the first n_1 sectors adjust prices in order to preserve profit margins while the remaining $n_2 = n - n_1$ sectors absorb cost increases. Let us consider the $n \times n$ matrix A of input-output coefficients in partitioned form:

$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

where the submatrix A_{11} is of dimension $n_1 \times n_1$, A_{12} is $n_1 \times n_2$, etc.; similarly, we partition $P = [P_1; P_2]$, and so forth. The matrix equation explaining prices in the margin-preserving industries is

$$(10) \quad P_1 = P_1 A_{11} + P_2 A_{21} + M_1 + W_1 L_1$$

$$(11) \quad = (P_2 A_{21} + M_1 + W_1 L_1)(I - A_{11})^{-1}.$$

Since the last n_2 sectors are cost absorbers, the vector P_2 is exogenous. If we let the n_1 component column vector $X_1^* = [x_i^*]$ denote $(I - A_{11})^{-1} Y_1$, the market value of all goods and services produced in the economy is

$$(12) \quad PY = P_1 Y_1 + P_2 Y_2 = (P_2 A_{21} + M_1 + W_1 L_1) X_1^* + P_2 Y_2$$

$$(13) \quad = P_2 (A_{21} X_1^* + Y_2) + (M_1 + W_1 L_1) X_1^*.$$

⁸ See footnote 5.

Substituting this last expression into equation (3) yields a new expression for the GNP deflator:

$$(14) \quad p = \frac{P_2(A_{21}X_1^* + Y_2) + (M_1 + W_1L_1)X_1^*}{P^0Y}.$$

If one of the first n_1 (margin-preserving) sectors autonomously adjusts its profit margin, the GNP deflator will obviously change by

$$(15) \quad \Delta p = \frac{x_i^*}{P^0Y} \Delta m_i, \quad (i = 1, 2, \dots, n_1).$$

This is smaller than our original estimate of the inflationary impact of a markup change by the proportion x_i^*/x_i —the fraction of the actual gross output of the markup increasing sector that is not used, directly or indirectly, by cost-absorbing industries in the production of the final bill of goods. On the other hand, the sector initiating the inflation may be a cost-absorber; that is, it increases its price and allows any subsequent induced cost increases to erode its gross profit margin. From (14) we see that in this case

$$(16) \quad \Delta p = \frac{x_i^{**}}{P^0Y} \Delta p_i, \quad (i = n_1 + 1, \dots, n),$$

where

$$x_i^{**} = \sum_{j=1}^{n_1} a_{ij}x_j^* + y_i$$

is the i th element of the column vector $X_2^{**} = A_{21}X_1^* + Y_2$. The quantity x_i^{**} is that component of x_i that is not used, directly or indirectly, by cost-absorbing industries.

In utilizing our first proposition to estimate that the effect of a \$6.00 increase in the price of steel would raise the GNP deflator by 0.11 per cent if all other sectors observed the guideposts, we were neglecting the possibility that the rise in prices precipitated by this action might raise the costs of inputs to steel and prevent the margin on steel from rising by a full \$6.00 per ton. A \$6.00 price increase under these circumstances means that steel is a cost-absorbing sector, and our estimate overstates the effects of the price increase by the ratio x_i^{**}/x_i , where x_i^{**} is the output of steel that is not used, directly or indirectly, as inputs by the steel industry.

III. Attempts to Preserve Real Shares

Our suggestion that a \$6.00 per ton increase in the price of steel would have raised the general level of prices by about one-tenth of one per cent was based on the assumption that money wage rates and profit margins in other sectors are unaffected by increases in prices, as required by guidepost policy.

In this section we explore the consequence of attempts in other sectors preserve real wages or profit margins following an exogenous price increase. We begin by considering the effect of attempts by labor in all industries maintain real wage rates. We will show that:

If all money wage rates adjust to the increase in the cost of living, the original inflationary impact of an increase in the gross profit margin will be multiplied by the reciprocal of one minus labor's share.

Since labor's share in U. S. output is roughly three-fifths, the inflationary impact of a \$6.00 per ton increase in the price of steel would have been about 0.27 per cent instead of the 0.11 per cent, if all wages adjusted to the price increase.

This revised estimate relies on the assumption that movements induced in the cost of living index are about the same as the changes in the implicit GNP deflator so that the vector of industry money wages is:

$$(17) \quad W = pW^0,$$

where the scalar p is again the GNP deflator and W^0 the vector of initial money wage rates. Substituting (17) into equations (4) and (3) yields:

$$(18) \quad PY = (M + pW^0L)X,$$

and

$$(19) \quad p = \frac{(M + pW^0L)X}{P^0Y}.$$

Hence,

$$(20) \quad p = \frac{MX}{P^0Y - W^0LX} = \frac{MX}{P^0Y} \left(\frac{1}{1-\lambda} \right)$$

where

$$\lambda = \frac{W^0LX}{P^0Y}$$

denotes labor's share.

The inflationary effect of a change Δm_i in the markup of sector i is therefore:

$$(21) \quad \Delta p = \frac{x_i \Delta m_i}{P^0Y} \left(\frac{1}{1-\lambda} \right).$$

If only certain portions of the labor force maintain real wage rates as prices rise, λ in equation (21) corresponds to that fraction of GNP represented by their money wages.

More generally, equation (21) reveals the effects of the preservation of real gross profit margins and wages in specific industries, once λ is appropriate

ately reinterpreted.⁹ Suppose, for example, that while labor and producers in the manufacturing sector, other than steel, observe the guideposts, prices and wages in nonmanufacturing sectors adjust so as to preserve real shares. Under these circumstances, the inflationary impact of a \$6.00 per ton increase in the price of steel would be considerably larger than our initial estimate suggested. Since gross product originating in manufacturing is roughly one-third of GNP, $\lambda = \frac{1}{3}$ and a \$6.00 steel markup increase in these circumstances would raise the GNP deflator by approximately:

$$\Delta p = .1065\% \left(\frac{1}{1 - \frac{1}{3}} \right) = 0.32\%.$$

Following the procedure set forth in Section II, this estimate can be adjusted to take account of cost absorption, i.e., deterioration in the real wage or profit margins in various sectors.

IV. Conclusions

Any analysis of cost-push inflation is incomplete, for the concept neglects the fact that price increases reduce real final demand unless offset by expansionary monetary or fiscal policy. Subject to this limitation, the propositions set forth in this paper provide a simple method for obtaining quantitative estimates of the inflationary effects of autonomous price increases, once the responses of other sectors are specified.

The extent to which a departure from the guideposts actually contributes to inflation depends upon both the magnitude of the violation and the sensitivity of the general price level to price adjustments made by the sector deviating from the rules of noninflationary behavior. We estimate that a \$6.00 increase in the price of steel in 1962 would have raised the GNP deflator by less than 0.11 per cent, *if* labor and firms in other sectors of the economy had observed the guideposts. This suggests that violations of the administration's guideposts by so called "key industries" have not in themselves constituted a clear and present danger to price stability.

Autonomous price adjustments that induce other sectors to violate the guideposts have a more substantial effect. For example, we found that the inflationary impact of a \$6.00 per ton increase in the price of steel in 1962 would have been 0.27 per cent if unions negotiated wage adjustments preserving labor's real share. Additional inflation would have been generated if firms in other sectors of the economy were induced to raise their profit margins. This suggests that the case for enforcing the guideposts must be based on the argument that price adjustments in key sectors constitute a danger-

⁹ An increase in a particular sector's margin will cause all prices to rise proportionately if all other sectors adjust their prices so as to preserve their real shares. This result, which is in conformity with classical general equilibrium theory, is derived by observing that in these circumstances equation (20) reduces to $\dot{p} = MX/m_i \dot{x}_i$, where i denotes the sector attempting to increase its margin, the only sector that suffers from money illusion. If no sector suffers from money illusion, $\lambda = 1$ and prices will rise indefinitely as the result of a sector's attempt to raise the real value of its margin.

ous precedent which will generate inflation by precipitating wholesale violation of the rules of noninflationary price behavior.

Rejoinder

We wish that finished steel mill product prices had not doubled from 1947 to 1957—or at least had risen no more than prices generally. We would have been spared a lot of writing. The steel companies would have been spared losses of markets to other materials, deterioration of their profit position, and the public attention which they do not welcome. Steel workers—whose wage increases contributed to the inflation in steel in the mid-1950's—would have been spared large job losses and a weakening of their bargaining position. And the economy would not have suffered a loss in its international balance of trade of \$1.25 billion in steel alone between 1955-57 and 1965, plus additional losses in machinery and other metal products.

Our steel study of 1959 pointed out the obvious, that steel prices rose a great deal and that they had a pervasive effect on industrial product prices. Our methodology, using input-output, had some novelty, but the main points could have been made by simpler computations.

The paper has spawned a succession of other papers, some serious pieces of work, others not. (Our favorite reply is U.S. Steel's Jules Feiffer-like ad in a recent *New Yorker*.) The Brainard-Lovell paper does fall in the serious category, but not as serious as they think. Two of their three main points are

not particularly novel or new, and where they venture into new territory they are not quite serious.

Our comments follow the organization of their paper.

1. The logic of Proposition I has long been recognized. The arithmetic proposed by Brainard-Lovell was actually applied in our paper in footnote [2]. Charles L. Schultze's analysis to which they refer is based on essentially the same scheme. And Martin Bailey presented a very similar mathematical argument in 1962 [1].

Brainard and Lovell's empirical point is that a \$6 per ton increase in 1962 could have raised the GNP deflator by *only* 0.1 per cent if all other sectors followed guideposts. This seems like a tiny number, but if a single, price change can raise the economy's over-all price level by 0.1 per cent, that is quite astonishing. During the period of industrial price stability from 1959 to 1963, the over-all GNP deflator rose by 1.3 per cent a year mainly due to the rise of the indexes for construction, services, and government. Because the deflators for construction and government are price indexes of inputs rather than outputs, this figure overstates the price rise of that period. From 1963 to 1965 the GNP deflator rose at an annual rate of 1.8 per cent, or an extra $\frac{1}{2}$ per cent. And more recently the rise in the deflator accelerated to $2\frac{1}{2}$ per cent. If the difference between price stability and inflation is only about one percentage point in the GNP deflator, then the Brainard-Lovell findings should make us look out for steel price increases.

Brainard-Lovell also raise once more the old issue of the GNP deflator vs. the wholesale price index as an indicator of inflation. Both have their merits and their faults. The GNP deflator has substantial upward bias because its government and construction components are largely based on input rather than output prices. These two sectors account for almost half the rise in the period 1959-1963. The rest was mainly in services, another sector where prices are hard to measure. And these are all sectors with little direct participation in international trade. So this index is not a good base for measuring the significance of changes in specific industrial prices.

The over-all wholesale price index suffers from a kind of "double counting" because it is weighted by the relative importance of sales, irrespective of whether these are in final demand or intermediate markets. For this reason our study gave equal stress to the impact on the wholesale price index of finished goods, where intermediate products such as steel have no direct effect at all.

But more important, and as Brainard-Lovell agree, the isolated price increase is not the end of the story. Several basic materials, including steel, aluminum, plastics, (and also foreign steel) are substitutes; a price increase in one of these materials tends to produce increases in the substitutes. So substitution is a two-edged sword as far as inflation is concerned. More generally, the various feedbacks and spillovers in product and factor markets are the essence of the inflationary process.

2. The second proposition is obviously correct. It says that, if some industries absorb cost increases and others pass them on, there will be less

inflation if the cost increases apply to cost-absorbing industries. Surely no one ever thought otherwise.

3. The third section is an attempt to take account of the wage side of a mechanical wage-price spiral, in which all of the price increases are passed on in higher money wages, and all of the wage increases are passed on in higher prices. This is essentially a form of multiplier process, in which the analogue to the marginal propensity to spend is the fraction of income payments going to wages. Nonwage income is the leakage.

The empirical result which emerges—a multiplier of 3 on the initial price rise because the wage share is $\frac{2}{3}$ —is an interesting illustration but not a serious estimate. The model leaves a good deal to be desired. The more its logic is extended to other incomes, the larger becomes this multiplier. For example, higher steel prices will raise the price of equipment, making for larger depreciation charges. And we know that wage determination is rather more complex.

4. The conclusion states “any analysis of cost-push inflation is incomplete, for the concept neglects the fact that price increases reduce real final demand unless offset by expansionary monetary or fiscal policy.” This commonly made statement overlooks the fact that a cost-push price increase simultaneously provides the increased income to validate itself. The increase of price does not directly cut purchasing power. It only transfers it. The beneficiaries of the cost-push price increase raise their own money income, thereby keeping total real purchasing power in the economy intact. A neutral fiscal policy, defined as absence of any discretionary action, does not offset the price increase except in so far as inflation may lead to an automatic increase in the full-employment surplus. Whether “expansionary monetary policy” is needed to permit the price increase to be matched by rising demand depends upon semantics. If a neutral monetary policy is defined as maintenance of a constant free-reserve target, a definition given weight by the monetary authorities, then a cost-push inflation will automatically lead to an increase of the money supply.

Lest we be misunderstood, we add that cost-push has been no more than a minor element in the recent increases of industrial prices. And steel prices were virtually stable in recent years. The steel price-wage episode of the 1950's might now best be turned over to the historians. The flood of imports and public concern have changed the behavior of steel prices in the United States. Perhaps this is one problem that has been solved.

Lifetime Income and Economic Growth: Comment

In a recent article [1], Herman P. Miller discusses the effects of economic growth on lifetime earnings. His main findings are:

1. The effects of economic growth are substantial and "the usual procedure for estimating lifetime income based on cross-section surveys tends to produce underestimates because of the failure to take future growth into account."

2. "... the impact of growth appears to be greater for young men than for those past the prime working years" [1, p. 834]. These findings are based on Table 2 of [1] in which Miller breaks the relative change in income of given-age cohorts between 1949 and 1959 down into "change associated with age" and "change due to economic growth" and finds that the latter is of a substantial magnitude and that it declines rather rapidly with age.

In Figure 1, $B - A$ is the rise in income of an age cohort over the decade 1950-60. This increase can be expressed in terms of the income of the cohort at the beginning of the decade and broken down into two components:

$$(1) \quad \frac{B - A}{A} = \frac{C - A}{A} + \frac{B - C}{A}.$$

The first component can be regarded as the age effect, as measured in relative terms along the earlier cross-section income-age curve. The second com-

FIGURE 1

ponent is in fact what Miller treats as the "growth" effect. However, a complete breakdown of the relative rise of income of an age cohort over the decade is

$$(2) \quad \frac{B - A}{A} = \frac{C - A}{A} + \frac{B - C}{C} + \left(\frac{C - A}{A} \right) \left(\frac{B - C}{C} \right),$$

where $\left(\frac{C - A}{A} \right)$ may again be designated the age effect, $\left(\frac{B - C}{C} \right)$ may

be regarded as a pure growth effect, and $\left(\frac{C - A}{A} \right) \left(\frac{B - C}{C} \right)$ is an inter-

action component. Miller's measure of the "growth" effect is the sum of the pure growth effect and the interaction component with the following results:

a. His measure is generally higher than the pure growth effect. This is because the age effect as observed in cross-section data is positive and relatively large over most of the span.

b. His measure of the "growth" effect will show a decline with age when the age effect is constant, will generally overstate the decline when it exists, and may understate a rise or even turn it into a decline. The reason is that the age effect, upon which Miller's "growth" effect was shown to depend, declines with age. This is reflected in the concavity of the log income-age curve as observed in cross-section data.¹

The advantage of measuring the effect of growth by $\frac{B - C}{C}$ rather than by $\frac{B - C}{A}$ is particularly clear in the case where economic growth is neutral

with respect to age. If neutrality is defined in terms of unchanging relative age differentials in income (i.e., the log income-age curve as observed in cross-section data slides uniformly upwards) then the growth effect as

¹ R_A is the relative change in income of an age cohort over a decade; R_A is the relative age effect in the cross section; R_g is the pure growth effect which is the relative change in income of an age group over a decade. Miller's measure of the growth effect, R_g^m , is

$$(1') \quad R_g^m = R_A - R_a = R_g(1 + R_a).$$

Differentiating with respect to age, a ,

$$(2') \quad \frac{dR_g^m}{da} = R_g \frac{dR_a}{da} + (1 + R_a) \frac{dR_g}{da}.$$

The first term is negative because of the concavity of the cross-section income-age curve. When the pure growth effect, R_g , is constant with respect to age, the second term vanishes, but R_g^m will show a decline with age. If R_g declines with age (dR_g/da negative), R_g^m will decline faster unless the age effect is negative and large. If R_g rises with age, R_g^m can rise faster, or slower, or even decline.

measured by $\frac{B - C}{C}$ will be, in the case of neutral growth, equal for all

age groups.² $\frac{B - C}{A}$, the measure used by Miller, will however show in

this case a decline with age. Miller did not see any inconsistency between his finding that "the impact of growth appeared to be greater for the young men" [1, p. 834] and his own observation that "the variation in income with age based on cross-section data [i.e., presumably relative age differentials in income] . . . has been found to be quite stable" [1, p. 840]. The case of neutral growth is particularly important because only then can we interpret the relation between income and age in cross-section data as the static life cycle. Neutrality is a necessary but not a sufficient condition for unequivocal measurement of the age effect along either cross section curve.

Table 1 presents a comparison between the growth effect as measured here, $\frac{B - C}{C}$, and as measured by Miller $\left(\frac{B - C}{A}\right)$. The first is calcu-

lated directly as the relative difference in the income of identical age groups between the two censuses, based on the data in Table 1 of [1]. Miller's mea-

² Alternatively, the effects may be defined in absolute terms with "neutrality" corresponding to a case where absolute age differentials in income are constant through time.

sure is based on columns (3), Table 2 of [1].² The pure growth effect is somewhat higher in the age group 35-44 than in older age groups but the decline, where it exists, is much smaller than reported by Miller, and in some cases there is actually an increase with age where Miller shows a decline. It is also interesting to note that the group least affected by growth is the group 45-54 and not the oldest group 55-64.

A discussion of the substantive issue of the relation of the economic growth to the shape of the income-age curve is beyond the scope of this note.

Engineering Production Functions and Capital-Labor Substitution in Metal Machining: Comment

I. *Engineering vs. Heuristic Production Functions*

For some time the theory of the firm has been subject to an unfortunate division: in the classroom we talk about production functions involving physical inputs and a physical output; in our empirical work we are content to estimate cost or production functions from value and accounting data.¹ The former have come to be called "engineering production functions,"² while the latter have been termed "index numbers of production" [3], "distribution functions" [4], and "surrogate production functions" [13]. Attempts to refine these empirical production functions to bring them closer to the physical production functions of the classroom have led to a mass of literature. The difficulties involve such questions as: Under what conditions may factors be aggregated [5]? Should capital be measured as a stock or service?³ Should there be corrections for price changes? (If so, should these entail weighting by (1) constant prices, (2) moving averages, or (3) labor time equivalents [15]?)

In an attempt to break out of this dualism and its set of problems, Mordecai Kurz and Alan Manne used "engineering data" to estimate

¹ For a review of the literature, see [17]; for a detailed discussion of the Cobb-Douglas function, see [12].

² The definition of an engineering production function is a bit more specific as given by Chenery [1]. Output is a function of engineering variables, i.e., the qualities or characteristics of inputs. Equivalently, an engineering production function is a relationship between a physical output and physical inputs where each input is a vector of characteristics [1, pp. 511-13].

³ For a discussion of these concepts, see Lave [10, Ch. 10, Sec. G].

capital-labor tradeoffs in the metal-machining industry [9]. The novel feature of the analysis was that output was measured by the numbers of operations (of each particular type) that could be performed on a particular machine during a work day. Since these observations consisted of output in physical units and capital in physical units (labor is accommodating), Kurz and Manne hoped to generate capital-labor tradeoffs free from the problems generally encountered in estimating production functions.⁴

In estimating Cobb-Douglas and constant elasticity of substitution production functions, Kurz and Manne measured capital as the purchase price of each type of machine. Inefficient observations, those inside the capital-labor-output frontier, were deleted from the analysis. In estimating the functions, dummy variables were used to take account of the difference between output tasks. For example, there were five classifications for the size of the piece being machined: very small to very large. These classifications, in the form of 0-1 dummy variables, are shown in equation (1):

$$(1) \log Y = b_0 + b_1s_1 + b_2s_2 + b_3s_3 + b_4s_4 + b_5s_5 + \dots + b_k \log K$$

where the s_i indicate the five size classifications, K is the purchase price of a particular machine, and Y is the number of pieces turned out during a normal working day. (Groups of dummy variables for shape, tolerance, and lot size were also used.) An observation might consist of the number (Y) of pieces of size 3 ($s_3=1$, $s_1=s_2=s_4=s_5=0$) which were turned out by a machine costing \$10,000 during a work day (Y and K are divided by L , the number of men working on the machine). When this equation was fitted to the data, the statistical results were good and the coefficients made economic sense (the implied share of labor in output was compared to Census estimates and the two were quite close).

Eirik Furubotn argued that equation (1) was not an engineering production function since capital is defined in terms of price, not physical units [6]. He also argued that the measure of capital (machine purchase price) is inadequate and "... the quantitative results obtained are open to question ..." [6, p. 515]. Furubotn contended that the analysis could not be corrected ("... the censoring rule is invalid as stated by Kurz and Manne, and incapable of useful revision" [6, p. 615]) since the valuation of capital is necessarily subjective depending on the expectations of entrepreneurs.

Is it possible to estimate an engineering relation of the sort defined in the classroom? Just what did Kurz and Manne estimate? How might their procedure have been changed?

II. Theoretical vs. Empirical Production Functions

Furubotn emphasizes the distinction between the physical production function of the classroom and the sort of function estimated in practice:

... if a *production function* is to be established, information on prices is not needed. The efficient technical alternatives can be separated from the total array of processes on the basis of objective physical criteria;

⁴ Other work along these lines includes [1], [2], [7], [14].

the problem here is technical rather than economic. Needless confusion is created whenever the distinction between these two levels of choice is blurred [6, p. 515].

In practice the technological relationships can not be kept so pure. A Chenery points out, the engineer is faced with a mushrooming set of possible input combinations, owing to the large number of possible materials that are relatively close substitutes [1, p. 509]. Unless alternatives can be ruled out the set becomes so large that there is no possibility of handling it empirically. (For example, a desk might be made of wood, steel, gold, diamonds, or many other materials; if the engineer attempted to consider all materials that would make a feasible desk, the number of alternatives would be too large to evaluate.) The engineer, according to Chenery, rules out inputs by assuming a set of prices. In contrast, the economist limits alternatives by aggregating inputs into two or three sets of factors, e.g., labor, capital, raw materials [1, p. 510].

Each of these simplifications leaves its mark on the estimated relation. The engineer's production function will continue to describe the efficient process only as long as relative prices are approximately constant. The economist's relation depends on each factor behaving as a Hicksian "composite commodity" (relative prices within each factor category must be constant) [8, pp. 33-34]. In addition, all relative technological relations between capital, labor, and raw materials must be essentially constant.

With a large number of inputs, and a moderately large book of technology "blueprints," it is extremely unlikely that a single, reasonably simple function would describe all efficient input-output combinations. Yet, it is just such a simple function which must be estimated in practice. Even neglecting the question of the constancy of the book of blueprints (neglecting technological change), only a part of the technology can be described, and that only approximately. In estimating a production function, one is estimating an approximation; it is important that the estimation procedure tailor the approximation to a particular use. Only if the biases and limitations of the data and estimation procedure are unimportant to the particular context can a useful relation be estimated.

III. *Capital-Labor Tradeoffs in Metal Machining*

To come back to the metal-machining context, the pure, physical production functional can be none other than the entire set of relations collected by Markowitz and Rowe [11]. These data, with which Kurz and Manne began their analysis, describe various physical outputs in terms of the labor and time required to produce them on a given machine; they are derived independently of prices. Unfortunately, the data are not very useful in this form. Without a scheme for aggregating or comparing the various machine tools, there is no way of summarizing the data and they remain 1,143 observations on 115 machines performing 129 tasks. Since these data were collected under the assumption of fixed labor-machine proportions, one cannot even get useful isoquants.

Simplifying assumptions are necessary before the Markowitz-Rowe data

can be used to estimate capital-labor substitution. Machines must be compared and so some sort of price weights are necessary. Kurz and Manne used purchase price of each machine tool, and so their relation gives an estimate of the tradeoff between labor and machine purchase price. This tradeoff is an extremely limited one, as Furubotn points out, since a machine costing one dollar more than another, but lasting five times as long, would be labeled "inefficient" (assuming both give the same output per labor hour). Such a limited tradeoff might be relevant for a firm with an extremely limited amount of funds for purchasing equipment.

To estimate capital-labor tradeoffs, Furubotn argues, present value, not purchase price, is the correct measure for comparing machines. Indeed, one must agree that purchase price is not likely to be a good surrogate for capital's services. But one must specify the nature of the required relation before capital's services can be measured.

Kurz and Manne decided to estimate an optimal efficiency locus rather than an "efficiency in practice" or "average efficiency" locus. This decision simplifies the analysis since it makes the problem of measuring capital more tractable. Which of the two measures (stock or service) will give the better approximation to capital's role and usefulness? Since it is the efficiency locus we are considering, we may assume that capital will be used efficiently. With full utilization and a fixed rate of interest, the two measures will be equivalent except for expectations about the future: what will be the rates of obsolescence, price change, and technological change? Furubotn is correct in arguing that entrepreneurs will answer these questions differently, and so the value of capital will vary between entrepreneurs. However, Kurz and Manne are again free to choose the "correct" or "perfect foresight" expectations since they are estimating the efficiency locus.

The Markowitz-Rowe observations were generated independently of price data; they represent an attempt to derive an exhaustive list of the operations that might be performed on 115 tools. No matter what set of prices is used to compare machines, some of these observations will be inefficient. What place should an observation inside the production frontier have in estimating capital-labor tradeoffs? As in a theoretical treatment, these observations must be deleted before fitting the production relation. However, the censoring rule must be specified carefully and must be relevant to the use to which the resulting estimates will be put. The estimates are likely to be quite sensitive to the criteria of efficiency.⁵

IV. *Changing the Kurz-Manne Procedure*

In an empirical study of the Kurz-Manne sort, a number of assumptions and approximations are required. An essential part of the study involves

⁵ The set of "correct" expectations will be manifested in the model by the choice of capital (machine) values. Machines whose values render them "inefficient" will be deleted from the analysis. A machine will be purchased only if its price is less than or equal to the present discounted value of the profit that would be realized by using this machine. Thus, an independent hypothesis emerging from the analysis might be that inefficient machines, ones deleted from the analysis for all tasks, should be left unsold in the market.

testing the implications of the estimates. Kurz and Manne tested their estimates by comparing the share of capital in value added (implied by the estimates) with capital's share as given in the U.S. *Census of Manufacturers*. The *Census* data are not pure and so the two "... cannot be compared directly ..." [9, p. 677]; but the figures are comparable and lend some confidence to the estimates.

A more direct way to test the estimated model might have involved assuming a price of labor (the price of capital is already in the model) and getting the implied prices and price differentials of each "task" (performing each machining operation). If the metal-machining industry is competitive and efficient, the prices implied by the model should be found in the market. Even if there is imperfect competition in the market, some of the prices ought to be correct (some of the tasks will be priced competitively) and all other prices should be above the predicted ones. Such a comparison (more than one hundred prices for comparison would emerge) should prove a sensitive one in testing the twin hypotheses of (a) competition and efficiency in metal machining, and (b) the reasonableness of the estimated model.

The last two comments are related to the Kurz-Manne statistical analysis. Dummy variables are used to take account of differences in size, shape, tolerance, and lot size of the piece being machined. As specified, the model cannot be estimated since it would give rise to a singular variance-covariance matrix [16]. Kurz and Manne follow the general procedure of excluding one variable from each of the sets of dummy variables and then using simple least squares. However, they do not note that the coefficients which are estimated will be the difference between the coefficient of each remaining variable and the coefficient of the excluded variable. Changing the excluded variable would have changed the number of "significant" coefficients.⁶

Finally, it should be noted that their estimation procedures are part of a covariance analysis. They have asked questions about the relation between the capital coefficient and the various tasks. Such issues are part of the general question of which groups of observations may be pooled to obtain parameter estimates of wider scope. Questions of interest include: (a) What sort of aggregation across machines or tasks is statistically permissible? In other words, is there a single model that describes all machine tools? (b) Just how many different capital coefficients and different intercepts should there be? (c) Is there really capital-labor substitution between different machines? Covariance analysis would provide answers to these questions.

V. Conclusion

The Kurz-Manne analysis represents a path-breaking attempt to estimate characteristics of the production function from engineering data. As with most pioneering studies, there were a number of difficulties and un-

⁶ Suppose $Y = b_0 + b_1s_1 + b_2s_2 + b_3s_3$, while $s_1 + s_2 + s_3 = 1$. Then $S'S$ will be singular and estimation by simple, least-squares techniques will be impossible. However, substitution is possible: $s_3 = 1 - s_1 - s_2$ and so $Y = b_0 + b_1s_1 + b_2s_2 + b_3(1 - s_1 - s_2)$; which simplifies to $Y = (b_0 - b_3) + (b_1 - b_3)s_1 + (b_2 - b_3)s_2$. Thus, one would estimate $Y = a_0 + a_1s_1 + a_2s_2$. Testing the significance of a_1 is equivalent to testing whether b_1 is significantly different from b_3 . If one chose to exclude an s_i whose b_i was quite different from the other b 's, all of the a_i would be "significant."

necessary limitations. Some of these were corrected by Furubotn; others are suggested here. In large part the problems stem from the failure to set out a specific question for analysis. It is not possible to estimate a general capital-labor substitution relation for metal machining, even given the existing technology. To render the data susceptible to analysis, some sort of machine prices are necessary, a censoring rule must be specified, and many other assumptions are needed. Since a range of plausible alternatives exists for each of the assumptions, the one actually chosen must be justified as being particularly appropriate to the purpose at hand.

Engineering Production Functions and Capital-Labor Substitution in Metal Machining: Reply

A point of universal agreement is that the production function of pure theory raises the most difficult problems for empirical work. If the concept is interpreted rigorously, an impasse is reached because the set of efficient technical alternatives for the typical commodity is virtually limitless and, hence, incapable of capture by any practical econometric technique. Professor Lave has emphasized, correctly, the need for empirical studies to focus on what is, in effect, a *partial* production function—i.e., a function defined subject to a series of price conditions and able to show some subset of the efficient alternatives. However, as the Kurz-Manne paper [3] makes clear, the introduction of prices does not eliminate all difficulties; indeed, new problems arise which seem almost as intractable as those from which escape is sought. And it is these latter problems that deserve further discussion.

I. Alternate Censoring Rules and their Deficiencies

The K-M censoring rule is misleading because it asserts that, whenever a number of machines have the same output per labor hour, the best choice is necessarily the machine which has the lowest price and involves the least investment outlay.¹ To escape the bias this efficiency criterion imparts to the production model, an alternate rule is needed. One possibility is to base the selection of technical alternatives on a comparison of machine-tool prices with the corresponding present values which can be estimated for the separate tools.² The latter approach permits choices to be made from the standpoint of optimization over time. Thus, reasonable weight can be given to factors which operate throughout the whole life of a capital asset and influence its effective economic contribution to the firm.³

The use of the present-value concept may help to resolve one difficulty, but immediately raises another. Obviously, the present value attached to any machine tool depends on the expectations held concerning the economic environment in which the input will perform. However, since different observers are almost certain to see future technical and market developments

¹ Thus, any quality of a machine which tends to raise its supply price, without simultaneously altering its one-period productivity, must be viewed as undesirable.

² There are, of course, problems connected with the use of the present value approach. In general, machines will involve different investment costs and have different lifespans; thus, additional assumptions about the investment plan are necessary to insure comparability of the alternatives. Further, questions arise about replacement policy and the extent of the planning period.

³ One implication is that choice of relatively high-priced machines is conceivable. The production function obtained need not be shaped by the odd strategy of investment minimization.

differently, varied estimates of present value are possible for a machine,⁴ and the problem of subjectivity appears. It follows that there can be as many production functions as there are entrepreneurs considering investment.

II. *The Optimal Efficiency Locus as a Solution*

The line of reasoning pursued so far leads to rather depressing conclusions about the possibility for deriving useful empirical functions. Lave is more optimistic. His argument is that both the investment-minimization bias and the subjectivity problem disappear when the Kurz-Manne procedure is interpreted as a search for an "optimal efficiency locus." In other words, if we assume continuous utilization of equipment at the technically optimal output rate, a constant rate of interest, and perfect knowledge of all relevant factor and commodity prices over the planning interval, the K-M censoring rule is said to be satisfactory. Presumably, the same machine tools will be selected as efficient whether choice is based on present value or one-period productivity. Subjectivity ceases to be a difficulty because each entrepreneur acts on the same information. That is, each individual knows the correct values of future prices and, if rational, will adjust his production plans accordingly—with the result that uniform behavior emerges.

This defense of the K-M rule is ingenious; it is not, however, completely convincing. Even granting a universe of perfect foresight, there is no reason to believe that machines requiring the least capital outlay will always be optimal. For example, knowledge of future market conditions might indicate that relatively durable, and hence expensive, machines are preferable to less-durable units. While the arbitrary assumption of full utilization of equipment may make adaptability characteristics unimportant, machines possess other properties which have significance for the investment decision. Differences in safety, reliability of operation, ease of maintenance, etc. count for something, and thus conditions may easily be such that greater capital outlays rather than lesser outlays are desirable. One can assert that investment minimization is the best policy to follow in defining the production function, but the perfect-foresight model does not necessarily imply this.

Quite apart from the criticism just noted, there is a serious question concerning the usefulness of a model based on the idea that entrepreneurs are in possession of perfect knowledge of future events. In the limiting case, the economic system would have to be free of both primary and secondary uncertainty. But this conception of the world is purely theoretic. Merely to eliminate secondary, or social, uncertainty would require a complete set of forward markets [2, pp. 141–44], so there is no practical way of approaching the state where all entrepreneurs act alike. The fact is that, by tying such rarefied theoretical conditions to the K-M production function, the function becomes a very specialized construct. And, in consequence, there is a real problem as to where it can be applied. Since the assumptions of the "optimal efficiency locus" will not be met in the real world, the alternatives it shows

⁴ The productivity of a machine tool also depends on the precise nature of the technical organization into which it is fitted. See [1].

for capital-labor substitution need not correspond to those seen (and acted on) by the average entrepreneur or government planner. On the other hand, the concept is less general than the conventional production function and, thus, can play no great role in pure theory.

III. *Some General Implications*

If Lave's explanation is rejected, the situation reverts to the one described earlier. We can use the original K-M rule and accept the investment-minimization bias, or consider present values and run into the problem of subjectivity. Moreover, the difficulty noted here transcends the specific case of production relationships in the metal-machining industry; a decision on the type of censoring rule to be followed must be made whenever a partial production function is defined.

The conventional production function, which encompasses *all* efficient alternatives, can be established (in principle) without recourse to price data. By contrast, a partial function demands the stipulation of prices so that a censoring rule can be framed and the field of acceptable alternatives reduced. There is, of course, latitude for the introduction of various price sets. However, the existence of durable capital equipment in productive processes implies the need for multiperiod analysis. And, in general, the information necessary to define a partial production function includes not only the current prices of capital goods but a complete array of factor and commodity prices for all dates to the planning horizon.⁶ In short, what is required is just the kind of information which is impossible to know with assurance, and thus a large measure of uncertainty must attach to any production relationship drawn up with the aid of price data.

EIRIK G. FURUBOTN*

* A production function is supposed to show the greatest output obtainable from any given input combination. However, in the stock-flow or multiperiod case, both the physical output produced and the types of cooperating inputs used may change over time. Thus, a comparison of input combinations involving capital goods can become quite complex. In effect, dissimilar time streams of outputs (and inputs) have to be contrasted. The only way to evaluate such heterogeneous mixes is to convert all elements to discounted dollar sums; but this kind of undertaking requires the assumption of a multiperiod price structure.

BOOK REVIEWS

General Economics; Methodology

Essays on Economic Policy, Vols. I and II. By NICHOLAS KALDOR. New York: Norton 1965; London: Gerald Duckworth & Co., Ltd., 1964. Pp. xxi, 293; xxii, 320. \$7.50 each; 50s.

The task of the reviewer of Nicholas Kaldor's *Essays on Economic Policy* is simplified by the fact that the author has included his own review of the volumes in two introductory chapters. He explains what the articles are about and why they have been included.

One reason for inclusion is to review the author's intellectual progress from pre-Keynesian economist to a neo-Keynesian Kaldorian. Thus, Volume I begins with the 1935 article, "Wage Subsidies as a Remedy for Unemployment." Kaldor explains that no one in his right mind would now agree with the analysis of the article. It is based on the erroneous premise that it makes sense to speak of the real marginal product of labor in the short run. And, even if that assumption were not erroneous, the real wage could not be equal to the marginal product since, in times of depression, the marginal product is greater than the average product. Keynes in the *General Theory* made the assumptions that Kaldor now rejects, and I continue to find it a useful starting point. Despite the author's disavowal, I continue to admire the article as the best treatment of the subject I know of, notwithstanding Kaldor's new theories concerning such matters.

The second essay, "Quantitative Aspects of the Full Employment Problem in Britain," already published as an appendix to Beveridge's *Full Employment in a Free Society*, must arouse nostalgic memories in the countless economists round the world who were working on the same problem, at the same time, on the same lines. As one of those, I express my admiration for Kaldor's performance. Incidentally, the article is a useful reminder to those who regarded the U.S. tax cut of 1964 as a new discovery in economic analysis. The achievement in 1964 was that the President and the Congress were persuaded to accept the economic analysis as the basis for political action.

Kaldor observes the economic scene with the cold detachment of a Ricardo. While he is presumably attempting to design the kind of world he would like to see, ideology and emotion rarely intrude into the argument. He is a functionalist rather than a sentimentalist. No public tears are shed for the starving poor. A man may be as rich as Croesus provided he invests rather than consumes. In fact, as with Ricardo, capitalist savings are virtually the sole source of private saving. Landlords are not wicked; they are not functional. Like Ricardo also, great intellectual power is exhibited with an absence of wit, a solemnity of purpose, and hasty drafting. Spectacular conclusions emerge from the "stylising" (to use Kaldor's word) of facts and premises.

Flattering though comparison with Ricardo must be, Kaldor may not like

it, since he claims to have solved the problem of distribution and growth which baffled the classical economists; and which in his view the marginal productivity theory cannot solve under conditions of technological change. Since this theory underlies many of his policy recommendations, it is incumbent on the reviewer to comment on it. Economists have been saturated with variants and elaboration of Kaldor's theory in recent years. But the central ideas remain unchanged, and presumably the 1958 model, now republished, is still held by its author to be valid.

The classical economists, Ricardo and Marx, said that savings came from profits, and that the profits share in national income determined the rate of investment and, hence, the rate of growth. Kaldor stands them on their heads. He argues that the full-employment rate of investment and, consequently, the rate of growth, is determined by the "technological climate," and is independent of profit rates, interest rates, and wage rates. At the same time wage earners generally save nothing, profit receivers save a fixed proportion of their incomes.

With the economy held at full employment, Keynesian Multiplier processes establish a rate of saving equal to the predetermined rate of investment. Since the multiplier cannot work on output, which is fixed in the short run, it must work on the distribution of income. The argument leads directly to the dramatically simple formulas; $\frac{P}{Y} = \frac{1}{a} \cdot \frac{I}{Y}$ and $\frac{P}{K} = \frac{G}{a}$, where P = profits;

Y , real output; K , the stock of capital; G , the rate of growth; and a , capitalists' propensity to save.

In short, the profits share, and, consequently, the wages share and the rate of profits, and the rate of growth are determined by the technological climate and the capitalists' propensity to save.

The consequences of the theory are alarming—if capitalists want to increase their share and the rate of profits, all they have to do is to increase consumption. Their profits will rise correspondingly and the wage earners will pay for their Cadillacs. On the other hand, if wage earners decide to save, their share will be reduced; and the rate of profits will increase. The savings of the workers will go to support not investment, but capitalist consumption. We have learned over the years to accept topsy-turvy economics. But this theory imposes new strains on one's credulity.

I do not mean by these remarks to imply that there is not much of value in Kaldor's theory. In fact, it has much in common with Schumpeter. The innovator cannot, in the nature of the case, base his decisions on close calculation of factor scarcities and marginal productivities. A classical or neoclassical theory is almost bound to underplay the vital effects of innovation and technical change. But recognition of that fact does not require the overthrow of all that has gone before.

Kaldor recognizes, however, that his redistributive process is constrained by lower limits to real wages and profits. Wages cannot fall below "subsistence," and profits cannot fall below the levels determined by "degree of monopoly." He does not show that these boundary conditions are, in general, inoperative.

If they are generally operative, we are back in a classical or neoclassical world. The supply of savings will have an influence on the amount and character of full-employment investment.

Furthermore, to assume a fixed capitalist propensity to consume seems to me wide of the mark. Corporations can and do alter their dividend policy in the light of their investment requirements. Decisions to invest can alter the rate of saving, but they may do this by altering the propensities rather than through bringing about Kaldorian redistributions. In my own work, I am content to assume that the distribution between wages and profits remains fairly constant, apart from cyclical disturbances.

Kaldor uses his theory in its unqualified form to arrive at important policy conclusions. He deduces that an increase in the rate of growth is likely to be inflationary. According to the theory, it will involve a redistribution in favor of capital. Wage earners will then try to recover their former relative position by pressing for money-wage increases, and wage-price inflation will be the result. Most economists would argue that increased economic growth arising from productivity increases has effects on distribution that are not known in advance and, in any case, contributes to price stability by permitting increased money wage increases under conditions of stable prices.

Another application of the theory leads to the conclusion that inflation may be necessary in a slow-growing economy with a correspondingly low rate of profit. If the real rate of profit, determined by the model, is 4 per cent, and the money rate of interest is also 4 per cent, there is no margin with stable prices to allow entrepreneurs to cover risk and uncertainty. In such a situation, Kaldor recommends money-wage increases followed by price increases. For instance, 8 per cent inflation would provide a comfortable margin between the profit rate and the interest rate. While the real rate of profit and the distribution between profits and labor remains unchanged, the inflation permits the entrepreneurs to exploit the rentiers, on a permanent as well as a temporary basis. The question that Kaldor does not answer is how much of this treatment the rentiers will stand. It is quite clear that they will not continue to be happy with 4 per cent.

Kaldor complains (Vol. I, p. 189) that Keynes "who had such a remarkable intuition in this field, was curiously blind to the implications of continually rising money wages for the inducement to invest."

When we turn to Kaldor the tax expert, we return to the classical world, and Ricardo is on his feet again—especially with respect to underdeveloped countries. Savings again become the main determinant of investment and "taxation (and other compulsory levies) provides the most appropriate instrument for increasing savings for capital formation out of domestic sources" (Vol. I, p. 226). Here, the boundaries of the growth model have clearly been reached. In fact, he may well carry his point of view too far. Like many "development economists," he considers agriculture to be a large untapped source of revenue. The record of countries that have attempted to finance industrialization by taxation of agriculture is not reassuring.

In addition to raising resources for development, Kaldor regards progressive taxation measures as a major and necessary instrument of redistribution of

income and wealth "as the only alternatives to Lenin or Mao Tse-tung." Economists are rarely given opportunities to test their ideas in the "laboratory." Kaldor is an exception; his tax proposals have aroused political controversy and sometimes disturbance in India, Ceylon, Mexico, Turkey, Ghana, and British Guiana. As he wryly says, "The power, behind the scenes, of the wealthy property-owning classes and business interests, proved to be very much greater than the responsible political functionaries suspected." Landlords and businessmen had evidently read somewhere that the power to tax is the power to destroy. But the record is still incomplete. Some of them may wish they had heeded Kaldor when they get Mao.

I have not left myself enough space for a detailed review of the essays concerned with international problems. The earlier essays are concerned with the still-unsolved problem of reconciling domestic full employment policies with external balance. Kaldor is far more tolerant of direct import controls and bilateral arrangements than many economists. He does not discuss the possibility of floating exchange rates. His preference is for a scheme of automatic compensatory finance that will permit countries to finance their deficits on a basis that is largely automatic.

The problem that concerned Kaldor at the end of the 1940's was different from the one that preoccupies economists today. He, like many of us, was then concerned with the international consequences of a depression in one or more of the industrial countries, which would reduce the demands of those countries for exports from the rest of the world and hence plague other countries. Such countries would then receive financial assistance to help them cope with events beyond their own control.

The record of the intervening period has shown that deficits arise largely from the inflationary consequences of the country's own internal policies. In that event, the granting of automatic credit could enable the inflating country to exploit the rest of the world. Kaldor was not alone in failing to foresee the inflationary tendencies of the contemporary world, which have resulted in part from the types of policy he recommends. But not everyone republishes his 15-year old essays without modification or reconsideration.

A large part of the second volume is concerned with the alleged economic disadvantages of primary producing countries. Kaldor has struggled valiantly to devise commodity stabilization schemes and commodity agreements that are generally acceptable—with no more success than anyone else. The volume includes a proposal for a commodity reserve currency, prepared jointly with A. G. Hart and J. Tinbergen. It would be inappropriate for me to attempt to comment on this highly interesting proposal in the present review.

Whether or not one agrees, it is an exhilarating experience to observe Kaldor's unquestioned analytical ability applied to concrete problems. But the aspiring policy adviser will feel disconcerted about the power of logical argument to exert a direct influence on the course of events. Most advice is effective only when it goes in the same direction as the political tides. But one has the feeling that some puckish streak in Kaldor prevents him from giving his proposals a fair chance. In his report on Chile, which was presumably intended to influence the Chilean government, he states:

In the circumstances, the general presumption must be that neither from the point of view of economic growth nor of social justice did these [direct economic] controls yield any net benefit as compared with what the situation would have been if the allocation of resources had been left to the blind operation of market forces. There can be few fields of political action where the willingness of governments to prohibit and to prescribe is so out of proportion to the intelligence at their command as to what ought to be prohibited or prescribed. The application of detailed controls in capitalist economies is often no better than quack medicine. There is a great deal of straightforward corruption which goes to nullify the intended effects of detailed physical controls and yet leaves behind an unnecessary amount of social and economic rigidity" [Vol. II, p. 235].

Without question, Kaldor has the courage of his convictions. Whether he is adept at the art of persuasion is a different matter.

ARTHUR SMITHIES

Harvard University

Memoirs of Capitalism, Communism, and Nazism. By CALVIN HOOVER. Durham, N.C.: Duke University Press, 1965. Pp. x, 302. \$8.50.

Economists have not customarily written their memoirs. I can recall only a few, of which J. S. Mill's classic *Autobiography*, Alvin Johnson's interesting *Pioneers Progress*, and John Ise's *Sod House Days* come readily to mind, and the last was concerned more with the life of Ise's parents than with his own. This is not as it should be. Lawyers regurgitate their briefs and extol their life in court, while doctors dwell fondly on their past operations. Why shouldn't economists have their say?

The book before us is a nice blend of personal reminiscence, the development of ideas, and description and analysis of the part-time career—but very extensive at that—of a public servant. Hoover came from a low-income family in Illinois—his father was a section foreman on the Minneapolis and St. Louis railway—and his tender years were not very tender. Since the reviewer also spent some time as a section hand he can testify that there is no better spur to the desire to advance oneself than working on a tired railway roadbed under a Midwestern sun. Hoover describes his difficulties, despite the assistance of a devoted family, in getting a high school education and dwells, with forgivable nostalgia, on the three years spent at Monmouth College before he joined the army and sailed for France to participate actively in the last few months of World War I.

After the war Hoover took up farming but soon decided, as so many have before and since, that there are easier and more profitable ways of making a living. One is reminded of that other Middlewesterner, that haberdasher from Kansas City, who also demonstrated that one of the routes to public advancement is inability to meet a payroll. After finishing his undergraduate work at Monmouth, Hoover, now married, decided to do his graduate work at Wisconsin on the advice of one of his teachers that "the economics department of the university was probably the best known in the United States." Here he came particularly under the influence of John R. Commons and Selig Perlman. Although his special field was labor problems, Commons awakened his interest

in economic history, and his first published work, in the *Quarterly Journal* in 1926, was entitled "The Sea Loan in Genoa in the 12th and 13th Centuries."

Before completing his work for the Doctor's degree Hoover accepted a position in the School of Business at the University of Minnesota, where he reports that "Professors Garver and Hansen went a long way in compensating for the deficiencies in my training in economic theory up to this time." Despite this encroachment of orthodox economics, however, one can justly say, surveying the full sweep of Hoover's work, that the Institutionalists of Wisconsin left a permanent impress.

After two years at the University of Minnesota he accepted a call as assistant professor to Duke University where he has served for over forty years. The relation between Hoover and Duke University seems to have been a singularly happy one. The University was extraordinarily generous with leaves of absence for research and government service and, in turn, Hoover accepted his full share and more of University obligations. For 20 years he was Chairman of the Department of Economics and for ten of these years Dean of the Graduate School. Greater love than this hath no man.

Most of the book is devoted to his activities during leaves of absence from the University in the Soviet Union, in Germany, and in the service of the government. Hoover's central intellectual and moral interest has been the life of man under the totalitarian regimes of Communism and Nazism as compared with Western Capitalism. It is a theme that has run through his major books and much of his other writing. It appears in his first book, *Economic Life of Soviet Russia*, reappears in his second, *Germany Enters the Third Reich*, is carried forward in *Dictators and Democracies*, and is stated in mature reflection in *The Economy, Liberty and the State*. The mixture of personal reminiscence and analysis of the political economy of the various regimes he subjected to study makes of his memoirs a sort of *histoire raisonnée* of the twentieth century.

Hoover's entry into government service came during the New Deal days of the 1930's. He describes himself as an early Keynesian convinced even before the appearance of the *General Theory* in 1936 that "a general deficiency of demand, such as existed during the Great Depression, could be cured by massive creations of purchasing power through deficit financing." In late 1933 he accepted an invitation from Rex Tugwell to become an economic consultant to the Agricultural Adjustment Administration. Here he came in contact with a group of people whose diversity of background, outlook and personality was not to be matched until his later association with the O.S.S.; among them Henry Wallace, Chester Davis, Jerome Frank, Lee Pressman, Fred Howe. In the course of time Hoover took over Howe's position as Consumers' Counsel in which position he reports that his attempts to protect the consumer by price regulation left him with a deep nostalgia for the free market. He returned to Duke in the academic year 1936-37, devoting attention during the next few years to the economic problems of the South and to writing and speaking in favor of preparation for the war he saw coming.

He entered government service again as a consultant to what later became the Office of Price Administration and, shortly after the United States de-

clared war, he joined the Office of Strategic Services. Hoover's life as an Intelligence Agent was more glamorous than that of most economists who temporarily entered that calling. After a few months in the Research and Analysis branch of the organization he joined the Secret Intelligence branch and was put in charge of operations in Scandinavia. Having contributed his mite to tearing down the German economy, he was soon to find himself, under Generals Clay and Draper, fighting off the minions of Morgenthau in order to build it up again.

Although later Hoover was to be called back into intelligence work for short periods and spent some time on the Marshall Plan and later aid programs, he has devoted most of the postwar years to teaching and research. Top management at Duke and his colleagues in the Department of Economics must have breathed a sigh of relief to have their wandering scholar on the ground once more. Hoover, as a matter of fact, was one of the first of that tribe of economists, now so numerous, who divide their time between public affairs and university life. In many cases scholarship suffers heavily or, if not that, attention to University affairs. Hoover, however, managed to publish eight books and innumerable articles while carrying more than his share of the load of academic administration. And no one can deny that his varied and colorful career has provided material for memoirs substantially more captivating than a more sedentary life would have been likely to generate.

EDWARD S. MASON

Harvard University

The Politics of Bureaucracy. By GORDON TULLOCK. Washington: Public Affairs Press, 1965. Pp. 228. \$4.50.

Gordon Tullock's book is an analytic study of the internal workings of hierarchical organization, purporting to refer to governmental and business units alike, but drawing most of its factual illustrations from his close experience with the U.S. Foreign Service. The work presents an informal model of hierarchy. Roughly the first half has a preponderantly positive role: how such organizations operate. The second half has a more mixed but preponderantly normative role: why they operate inefficiently, and what can be done to improve performance. The distinctive approach of the book is to assume that each member of the hierarchy is a rational utility-maximizer, and to examine how this affects the setting of work goals at the different levels of the hierarchy and the degree of fulfillment of these goals. The analytic unit is not the multiple pattern of a table of organization but the simple dyadic relationship—taken one at a time—of inferior to superior, superior to inferior, and peer to peer within the hierarchy. The approach carries the economist's method of the individualistic decision-making context into organization theory. This is part of a recent general stirring of interest, marked by the efforts of Anthony Downs, Buchanan and Tullock, and the present reviewer among others, in applying the general methods of economics to the explanation of political and other nonmarket forms of decision-making.

The tenor of Tullock's conclusion is rather pessimistic. Because of individualistic self-seeking throughout the organization there is likely to be

significant slippage between what is the ostensible function(s) of the organization and what actually goes on. Only in an ideal, unrealizable state will an organization be efficient—i.e., will its rewards and punishments and operating procedures be structured so that individual interests dovetail to achieve the leader's formulated goals. To a greater or lesser extent in real-world organizations, for every dyadic relationship self-interest will generate a divergence between the behavior of an inferior which maximizes his superior's utility and that which maximizes his own utility. Therefore, detailed supervision at every level is critically necessary for tolerable performance, since good faith or intrinsic teamwork cannot be assumed. But such supervision is generally severely hampered by the unavailability of dependable evaluational shortcuts and the excessive costliness of what cumbersome observational methods are available. So supervision is allowed to be inadequate and so an organization will be inefficient.

Worse than this, it is not simply that the cost of achieving organizational objectives will be higher than they "have to be" (in some sense), certain types of objectives can not be realized by hierarchical organizations at all! The more intricate and extensive is the coordination of activities needed to achieve the objective, the more inefficient will the hierarchical form of organization be, since coordination demands supervisory relationships, and each such relationship results in slippage-error. Moreover, the errors of one supervisory level are cumulated at each subsequent level. The more levels of coordination that are necessary, the greater is the multiplier of cumulated error. Some complicated tasks—and Tullock makes it clear that he believes this applies extensively to present governmental objectives—engender so much cumulative supervisory slippage that they literally cannot be achieved by hierarchical organization, no matter how large the organization. It rests with decentralized modes of decision-making, such as the market, to accomplish such tasks if, indeed, they should be tried at all. (In the last section of the book, however, Tullock does consider supervisory methods that could improve efficiency somewhat.)

Tullock's results are not only disturbing, they are highly perplexing. Economic resource allocation theory suggests that a desideratum for internalizing certain processes under a "single" decision-making roof—a hierarchical organization—instead of leaving them external to an enterprise with a relationship based on periodic market transactions, is the need for intimate extensive coordination or integration with other processes operated by the enterprise. In other words, the need for coordination makes hierarchy more attractive relative to the market, not less. The key to the anomaly seems to rest in Tullock's misleading identification of coordination with supervision. It is not the *coordination* of separate contributions that is necessarily erroneous, it is the inability of the supervisor to be objectively certain that *each* or *any one* of the *contributions* is what he really wants. To be certain he would have to *duplicate* the work of each of his operatives. It is this duplication for each and every component that is administratively impossible. Tullock's argument about *coordination* is misplaced.

How serious is his argument about supervision? It stems from the argument that inferiors can have incentives to perform their tasks in ways that diverge from what their superiors want yet without their superiors knowing it. (The argument that they are giving superiors what they want but which diverges from the *organization's* objectives simply shifts us to the question of why these supervisors then do not perform *their* tasks in ways that conform to what *their* supervisors want, which is the logical structure of the issue we are considering.) It is one thing to argue the hypothetical existence of such an incentive, it is another thing to establish the circumstances under which the incentive will be acted on and the systematic manner in which it will be employed. Without these it is extremely difficult to know how seriously to take the argument.

We do have treatments in the literature about systematic management incentives for nonprofit-maximizing behavior in large corporations, e.g., overemphasis on growth, conservative investment patterns, excessive liquidity. But Tullock does not help us here. A real weakness of the book is that he is constantly *asserting* the significance of inefficiencies, but without giving a careful analysis of its conditions and directions. Only toward the end of the book in the somewhat different context of supervisory improvement can some of these issues be read between the lines. They are not systematically or deeply developed in the positive analysis. Most of the illustrations he gives refer to the U.S. State Department. These may be true, and, indeed, attention to the special reasons why such inefficiencies should be expected to appear in this sort of bureaucracy would enhance the model. But Tullock does not carry the *analysis* (as opposed to the illustration) this far. If he had, and had called to our attention the extreme vagueness of the "output" of this "enterprise" and its highly unusual "production function," he would be unwilling to use it as heavily as he does as the example for bureaucratic inefficiencies in general.

There are grounds for believing that slippage is not nearly so serious as Tullock insists. The main reason adduced by Tullock for slippage is the inferior's desire to please his superior when the latter's lack of information or preconceived opinions would be disturbed by an honest decision. But surely reality-testing is not so far away for the superior in most organizations (*pace* State Department) that it is to *his* interests to be and remain importantly in error by encouraging his inferiors to make him vulnerable with respect to *his* superiors. In the absence of such problematic bullheadedness from above, there are important payoffs to the inferior to perform his job well. And this subject represents another weakness of the book, since, while so much is made to depend on rewards and punishments for each participant, the character of these stimuli is inadequately treated. (One of the results of this is an incomplete treatment of Parkinson's Law.) Almost no attention is given to the internal reward from seeking to do a good job. One is almost made to believe that an employee will deliberately add up every column of figures wrongly unless his supervisor is checking him over his shoulder. Similarly, Tullock discounts the use of persuasion by superior to inferior to underscore the goals of the organization. Empirical studies disagree. Meaningful participation, praise from

one's superior, and the harmonious relationship which these entail, are chief ingredients of "good working conditions"—surely an important reward for directing human effort.

Tullock's book is peppered with items designed to irritate readers who do not share his deep suspicion of government in the modern world, as well as being based on a misleading distinction which identifies the term "government" with "monopoly" and "hierarchical organization," and "economic" with "pure competition" and "market transaction." Notwithstanding these irritations and the limitations on analytic scope referred to earlier, the book does lay a provocative groundwork for, and provides some lively insights into, the study of bureaucracies. While it swaggers and poses a bit like Machiavelli and Castiglione, it beckons us to follow in with some of the heavier—but also more ponderous, alas—ordnance of modern analytic discipline.

JEROME ROTHENBERG

Massachusetts Institute of Technology

Price and Allocation Theory; Income and Employment Theory; Related Empirical Studies; History of Economic Thought

The Stationary Economy. By J. E. MEADE. Chicago: Aldine Publishing Co., 1965. Pp. 238. \$6.00.

According to the cover description, *The Stationary Economy* is intended to be "volume one of principles of political economy." J. E. Meade's treatment is unconventional and one must be careful to note just what is being attempted. The intentions are stated quite clearly on the cover: "A modern statement in the classical tradition, elegant and rigorous, of the basic concepts of economic analysis," and in the Preface: "There is thus a crying need for attempts to translate, as far as this can be done, precise mathematical results into less technical terms and to relate all the branches of economic analysis to each other" (p. 8). Meade delimits his framework sharply: "It [this first volume] is based on models of economic systems in which there are no capital goods, and in which consumers' tastes, technical knowledge, and the size and composition of the population are static" (p. 8).

Thus Meade states his intentions. The series is to be a comprehensive treatment of modern theory as it applies to the classical tradition. This volume represents an attempt to integrate and explicate (in clear and nonmathematical terms) those parts of modern theory having to do with the stationary economy (with no capital goods).

"A major function of our analysis in this volume will be to explain what economic efficiency means and to show how in the conditions now assumed an equilibrium based on the free operation of the price mechanism will achieve an economically efficient use of resources. But it will also be a major function of our analysis in this volume to point out that this 'efficient' equilibrium may also be a very 'inequitable' one" (p. 33). Beginning with the individual in the market place (the theory of consumer behavior), Meade goes on to describe market equilibrium. Then he develops, expertly and elegantly, the terms of

trade between shops and farms (under the assumption that total goods are fixed, but income distribution changes). The next step is to hold income distribution constant and vary the production of consumer goods, under conditions of constant cost (consumer tastes must have changed). The following six chapters deal with various cases of fixed factors and increasing cost; the last two of these chapters make a brief excursion into changes in technical knowledge (Meade assumed that technology and tastes don't change) and into fixed coefficient production functions. Chapter 12 is concerned with the efficiency and welfare issues surrounding the distribution of income. The last three chapters deal with planning in a socialist economy.

Perhaps Meade attempts too much in a short book. Certainly, he can do no more than introduce most of his topics. Unfortunately, there is no attempt to refer the reader to other works for further study: except for two casual citations in the Preface, no citation or reference appears in the book (there is not a single proper noun in the Index).

Little attempt is made at a comprehensive statement of the body of micro-economic theory. For example, in discussing the derivation of the consumer's preference map, there is no hint that various consistency conditions are necessary before the preference points can be integrated into a two or greater dimension iso-utility surface (the problem that caused Pareto so much concern). It seems strange (in a principles of economics) that, in examining income and substitution effects, Meade presents the method developed by Hicks, but completely neglects Slutsky's analysis. One searches in vain for modern consumption theory (beginning with the theory of revealed preference) or modern production theory (e.g., maximization under constraints and duals). Both of these areas would seem to be part of the analysis of the stationary state—certainly both could use a clear exposition. Does Meade succeed in translating and integrating modern theory? If so, the success can be only a limited one since Meade seems to have chosen to ignore many of the results of the last 35 years.

Meade states his intention of translating results into less technical terms. One will search in vain for a derivative, either in text, footnote, or appendix; one will search in vain for any mathematical statement more complete than a simple algebraic equation or geometric illustration. This framework imposes a distinctive character on the book. Of necessity, the arguments are closely reasoned and often tedious; they must be kept simple, with the focus on two, or perhaps three, variables at a time. In view of the importance of the geometry, it is unfortunate that the figures are never titled, the axes are not clearly labeled, and sometimes not labeled at all.

And yet in one sense the book has succeeded. The central argument is clear and there are few distractions presented to the reader in this logical progression from the individual to the planned economy. ". . . one should be extremely frank about the assumptions which are being made at each stage for each model. This will unfortunately make many students despair of a discipline which appears so unrealistic. But this risk must be taken. Any other course means that the economist bamboozles himself as well as his students" (p. 23). "The art of political economy is to choose models which combine simplicity with relevance to certain important features of the real world. The economist can never be sure that he knows the answer" (p. 23). One might question the

relevance of the analysis (since capital, imperfect competition, and changes in taste and knowledge are excluded), but one cannot question the quality of the exposition.

The book seems unlikely to displace the line of intermediate or advanced microeconomic theory books presently available—the lack of citations alone would insure that. Yet its potential usefulness is quite large. For the student who is confused, or a bit too glib with his sophisticated tools, the book will help gain a real understanding of the methods of economic analysis. Yet, despite this attempt to “translate precise mathematical results into less technical terms,” one cannot help feel “But mathematics is helpful.”

LESTER B. LAVE

Carnegie Institute of Technology

A Scheme of Economic Theory. By G. L. S. SHACKLE. New York: Cambridge University Press, 1965. Pp. xi, 209. \$7.50.

Professor Shackle has written a book of essays on the following subjects: general equilibrium, Marshall's use of short and long periods, Keynes's employment theory, Harrod and Domar on growth, Hicks on the trade cycle, the Austrian theory of capital, and the Leontief input-output model.

The string on which these themes are threaded is the notion that different concepts of time are used in the various theories. The differing treatments of time, though each legitimate for its own end, form, nevertheless, a hierarchy of sorts, the highest in the firmament being those which take seriously the problem of decision in an uncertain world.

I confess myself unable to grasp Shackle's concept of different time-concepts. But one can agree that theories vary in their assumptions about, and emphasis on, expectations and uncertainty. This seems to be the nub of the matter.

The essay on Marshall is perhaps the best. Shackle attributes to Marshall, as his “daring innovation” (p. 28), the use of equilibrium to analyze processes of change; for he took the classical idea of market price adjusting to natural price and transformed it into a theory of economic evolution. His method was to interpret the “period,” whether short or long, as something seen *ex ante* by the businessman. The long-run normal expectation, though constantly influencing business behavior, is itself constantly evolving under the pressure of events, so that the classical stationary state is never attained.

Keynes inherited Marshall's use of the equilibrium method but, more impressed by the uncertainty clouding the future of business, thought of long-run expectations as so liable to sudden catastrophic shifts that no formal explanation of them could be attempted. In Keynes they become nothing more than a highly unstable parameter of the short-run equilibrium. Shackle's exposition of Keynes is praiseworthily explicit about expectations. But it might have been clearer to the uninitiated if the propensity to consume had been formally introduced. We meet the marginal propensity, but are not told that it is the derivative of consumption as a function of income.

Shackle seems to have missed an opportunity to relate Harrod's concept of warranted growth to the Marshallian idea of evolving expectations. He has an

unfortunate misconception of the meaning of C in Harrod's Equation, $GC = s$. He thinks of it as a *technically required* capital-output ratio, not as an *ex post* quantity. He is therefore at a loss (p. 108) to say what extra function is performed by the warranted growth equation, $G_w C_r = s$, and what can be meant by a difference between C and C_r , on which Harrod's instability thesis depends (p. 115).

Turning to the equation for natural growth, $G_n C_r = s$, we are told (p. 122) that if G_w is above G_n , growth at G_n cannot be maintained. There will be a cumulative slump. On the other hand if G_w is "far below" G_n , involuntary unemployment will appear and quickly grow. We are in for a cumulative slump either way, then.

Hicks is praised for his ingenuity, but gets low marks for having the accelerator, still lower for having autonomous investment, growing at the natural rate, and lowest of all for having a self-contained cycle model. Apparently investment is so unsystematic *in principle* that it is hubristic to build a model in which investment is a determinate function of other variables in the system.

Shackle's dislike of closed dynamical systems is partly philosophical. They are "an abstract representation of perfect determinism," and are unfavorably contrasted with Keynes's "conception of the unpredictable caprice of things" (p. 185). The nature of his anxiety is not altogether clear. It seems not to be such that a stochastic reformulation would allay it. Yet he must be aware that no prediction is possible unless the model is complete, that even the predictions of a complete dynamical model are conditional statements, and that predictions can be of value notwithstanding their "falsity," because they may be sufficiently accurate for the purpose in hand.

He also dislikes *specific* dynamical assumptions, on the ground that there is always an infinity of alternatives to choose from. But is not this as true in statics as in dynamics? Are we without criteria for choosing between alternative assumptions, whether statical or dynamical?

This is not a book brimming with new ideas. The style is heavy with simile and metaphor, and is not always perspicuous. It makes somewhat exhausting reading. But the student may derive benefit, provided that he undertakes considerable preliminary study of the theories elsewhere.

H. ROSE

University of Rochester

The Economics of Inflationary Processes. By K. K. F. ZAWADZKI. New York: Frederick A. Praeger; London: Weidenfeld and Nicolson, 1965. Pp. 288. \$10.00; 50s.

In an article published a decade and a half ago Ralph Turvey¹ distinguished four basic types of inflation:

Type A Prices: Cost-determined;	Wages: Cost-determined
Type B Prices: Flexible;	Wages: Cost-determined
Type C Prices: Cost-determined;	Wages: Flexible
Type D Prices: Flexible;	Wages: Flexible

¹ "Some Aspects of the Theory of Inflation in a Closed Economy," *Economic Journal*, Sept. 1951, 531-43.

According to Turvey inflation is "a process resulting from competition in attempting to maintain total real income, total real expenditure and/or total output at a level which has become physically impossible, or in attempting to increase any of them to a level which is physically impossible" (p. 534).

K. K. F. Zawadzki's book, as the author readily acknowledges, is devoted largely to spelling out the implications of Turvey's models. Zawadzki's treatment has several distinctive features. First, it is highly abstract from beginning to end. The book contains no numbers, no references to specific countries or inflationary episodes, and only a bare minimum of special institutional assumptions. As a result the reader learns nothing about the relevance of the various Turvey-Zawadzki models to the real world. Second, despite its abstract and intricate nature, the exposition makes no use whatever of algebra or geometry. Fortunately the author writes in simple straightforward English and has organized his complex material with great care. Nevertheless the end product is neither easy to grasp nor, in my judgment, definitive. Third, except in a short introductory chapter, this book contains only a few skimpy references to other work. The literature on inflation, of course, is vast; in their survey article (*AER*, September 1963) Bronfenbrenner and Holzman cited nearly 200 contributions from the postwar period alone. Perhaps the greatest lack in this area is an integrative treatise. Zawadzki's book does not meet this need.

But let us turn from the omissions—after all, only the author can determine the scope of his work—and examine the book on its own terms. Chapters 2 to 5, comprising nearly half of the volume, deal with inflation in closed stationary economies. Each of Turvey's types of inflation is given a name and analyzed in some detail.

In *struggle-for-income inflation* (type A) both prices and wages are cost-determined; they adjust to the cost levels prevailing at the end of the preceding period. In *excess-demand inflation* (type B) prices adjust immediately to changes in demand, while wages follow with a one-period lag; in *labor-shortage inflation* (type C) the reverse is true. Both prices and wages are flexible in *fully open inflation* (type D). The discussion proceeds by taking up the various types of inflationary shocks that may initiate each inflation. Zawadzki then examines "the factors and forces which may make inflationary processes end towards a stable equilibrium at a finite price level" (p. 79), the speed of inflation, and the effects on relative prices.

The flavor of the argument can be apprehended if we take a quick look at the discussion of struggle-for-income inflation. The initial shock may take any of four forms: "(a) an autonomous wage increase resulting from the dissatisfaction of the workers with their real income position; (b) an autonomous increase in gross profit margins resulting from the dissatisfaction of the entrepreneurs with their real income position; (c) a decrease in the average productivity of labor; (d) an autonomous increase in costs other than labor costs" (p. 44). Unit costs rise under (a), (c), and (d) and therefore cause prices to rise in the next period; prices rise at once under (b). Since wages are cost-determined, they rise further as soon as prices rise; and so on. But the process is not likely to continue indefinitely. Either wages or prices may not

adjust completely to cost changes; there may be income redistribution toward high-saving groups; progressive taxation may generate a budget surplus for the government.

Zawadzki recognizes that a process of this type requires either a passive monetary policy or a passive velocity of circulation to finance the augmented money flow and he assumes without further ado that somehow this will come about. It is precisely here that many readers will begin to lose interest, for there is little reason to believe (at least in the United States) that either the supply or demand for money will passively accommodate such an inflationary process. Nor is this difficulty unique to struggle-for-income inflation.

In Chapters 10-14 Zawadzki turns to the analysis of inflation in open economies. He assumes that the external effects of inflation will be continuously offset by exchange depreciation. The problem to be explored is under what circumstances inflation permanently worsens or improves an economy's international position, as gauged by changes in its terms of trade. The results are rather inconclusive, and I shall not attempt to report them here.

The final four chapters deal mainly with the interrelationships between growth and inflation. Zawadzki's analysis of growth, in accordance with the modern vogue, focuses exclusively on investment in nonhuman capital. Hence the effect of inflation on growth depends on how it affects the propensity to save and the inducement to invest. Zawadzki believes that income redistribution because of inflation is extremely unlikely to increase the propensity to save since wages are apt to gain relative to profits. Leaving redistribution aside, Zawadzki argues that personal saving propensities are likely to fall, but that business saving, as a proportion of profits, will probably rise enough to produce a net rise in the propensity to save for the economy as a whole. The effects of inflation on the inducement to invest are harder to analyze, but Zawadzki believes the net impact is more likely to be favorable to growth than not. On the whole Zawadzki gives some very cautious support to those who believe that inflation will stimulate growth. But he ends his book with the thought that there are "no grounds for the belief that a mild inflation is a simple and costless vehicle of economic progress" (p. 283).

RICHARD T. SELDEN

Cornell University

Die Grundlagen der Theorie der Preisdifferenzierung. By ULRICH W. ELLINGHAUS. Tübingen: J.C.B. Mohr Verlag, 1965. Pp. 275. DM 40.

Practical experience led the author to the conclusion that traditional price theory cannot include certain price strategies which play an essential role in modern economies. Therefore, no satisfactory explanations or guidelines, applicable to the real world, can be offered. Ulrich Ellinghaus is of the opinion that with the help of new analytical methods it will be possible to arrive at equilibrium conditions which are of greater practical value for a world in which *human beings* produce and consume. The traditional theory assumes that economic subjects establish contacts among themselves only through markets and with conflicting interests as the prime motivational factor. However, in reality, many types of individual and social relations exist, and a degree of

interdependence creates a common economic interest. Price formation is influenced by such circumstances and the reaction of individuals to the economic process cannot be explained by models in which a specific behavior is axiomatic. Economic behavior is based on certain social structures and must become a part of such models.

The new methods which the author wants to introduce and to apply to the problem of price differentiation are game theory and economic morphology. He selected price differentiation because he sees in it an important aspect of the circular flow within the economy. Accordingly, the first three chapters of the book are devoted to definitions of terms and methodological questions. Only the last two chapters deal with price differentiation specifically.

According to Ellinghaus, price differentiation exists when different quantities are demanded and paid for the same economic good or service during one single period of time and at the same location. Differences in prices caused by transportation costs are excluded. The term "price discrimination" is reserved as a *terminus technicus*, for special and exceptional cases. The purpose of the economic models is explained, followed by a careful description of various types of models. Special attention is given to the general equilibrium concept and the contributions of Walras and Pareto. The production and distribution concepts are used to compare equilibrium models with input-output relations. Game theory which is described in some detail.

Ellinghaus comes to the conclusion that game theory together with morphological methods alone make it possible to include the conflict of individual decisions in the analysis. Of particular interest is what the author has to say about economic morphology. Whereas models are used for abstract isolated typical symptoms, morphology is concerned with micro- and macroeconomic structures and forms. However, it is not sufficient to describe and classify these structures, but it is essential to expose the causality of their existence and their effects on economic behavior. Very interesting are the author's discussions of morphological concepts found in Eucken's and in Weisser's earlier works. The author also relates morphology to classical and neoclassical theory. Fully realizing the usefulness of these studies, he still finds that the automatic consequences are only the result of the fact that many variables are axiomatically eliminated and fixed. But in real life they remain variable. The behavior of the economic individual does not depend upon rational decisions alone, but also upon ideals, ethical attitudes, temperaments, traditions, etc.

Making use of game theory and including morphological methods, Ellinghaus analyzes price differentiation first in the microeconomic setting under conditions of monopoly, oligopoly, and regional price formations. In the framework of partial analysis he describes the processes of price formation and distribution. Various forms of price differentiation are introduced and supported by instructive examples which are used in typical models. The author shows which of these forms can be chosen under different market structures to reach optimality in terms of various goals. Finally he describes profit, quantity, and cost problems of price differentiation. But Ellinghaus is not interested in the purely microeconomic concepts alone. In the last chapter

he turns to macroeconomic aspects and offers a theory of price differentiation for both free-market and centrally planned economies, enriched by the use of the new analytical instruments. However, he is unable to produce at present a complete model (Totalmodell).

This, no doubt, is a remarkable attempt to expand the traditional price theory and to produce more satisfactory explanations for certain price strategies in modern structures. An English translation of the book would certainly prove useful. Unfortunately, it will remain the only contribution of this young and promising economist, who died from the consequences of a traffic accident.

LUDWIG H. MAI

St. Mary's University

Life of Adam Smith (1895). By JOHN RAE. With an introduction "Guide to John Rae's *Life of Adam Smith*" by Jacob Viner. New York: Augustus M. Kelley, Bookseller, 1965. Pp. 145, xv, 449. \$20.00.

A reprint of a book as well known as Rae's *Life of Adam Smith*, as welcome as it is, would not normally call for a review. In the case of this volume, it is not the reprinted material but, rather, the scholarly introduction provided by Jacob Viner that calls for reviewing. While the stated purpose of the "Guide" is to "... facilitate for the present-day reader the use of John Rae's *Life of Adam Smith*," it is more than what is implied by such a description. It is a critical and comprehensive survey of the progress of our knowledge concerning Adam Smith's life since the first publication of Rae's work. Apart from a new and definitive biography of Smith, nothing could be more helpful to the student of Adam Smith who has, in the past, been forced to check and cross-check the many books and articles among which recent (since 1895) discoveries about Smith's life are spread. In addition, however, to having brought existing facts together, Viner's incisive logic throws considerable light on the interpretation of these facts.

The "Guide" is divided into five sections, the first four of which, on grounds of both length and organization, can be called chapters. The fifth is a two-page chronology of Smith's life, followed by a brief bibliography of his publications. This, in turn, is followed by an index of names.

The first section, entitled "Introduction," opens with an extensive discussion of the difficulties of biographical research about persons living in the eighteenth century in general and Adam Smith in particular. The second and concluding part is a thorough outline of the major sources from which Rae gathered his material and from which more recent scholars have drawn further information.

The second section discusses the relationships between Smith and a number of his contemporaries. Rae's interpretations of these relationships are supplemented and corrected with the help of new discoveries by numerous scholars and by Viner's clever reinterpretation of the facts.

The third section discusses several aspects of Scottish economic life in Smith's time, i.e., the economic state of the Highlands, the licensing of physi-

cians, pin-making and nail-making, slavery in the Scottish mines, and his views or his apparent lack of concern with the problems involved. Although the entire section is interesting and not without importance, the discussion of the Highlands and slavery in particular seem rather distantly related to Rae's *Life*.

The fourth section, on Adam Smith's library, argues convincingly that a large number of books from Adam Smith's library have never been identified and that arguments concerning influences on Smith that are based upon the absence of a book or books from the lists of those known to have been in Smith's library can have little validity.

The Smith chronology and bibliography that make up the fifth section are references that the student of Adam Smith will find many occasions to use.

Many students of Adam Smith will welcome the opportunity to purchase a copy of Rae's *Life*. Even those with a copy of the original edition will find that Viner's introduction is worth the price of the reprint.

Economic History; Economic Development; National Economies

The Cambridge Economic History of Europe. Vol. VI, The Industrial Revolution and After: Incomes, Population and Technological Change. 2 Vols.

Edited by H. J. HABAKKUK and M. M. POSTAN. New York: Cambridge University Press, 1965. Pp. xii, 601; xii, 437. \$19.50 the set.

Somewhat like the Holy Roman Empire, which has none of the attributes of its title, this book is not restricted to Europe, to industry, or to after, but deals also with the world, with agriculture, and before the Industrial Revolution. This is misleading, but perhaps unimportant. What makes a greater difference is the permissiveness of the editors in giving their contributors free rein unquestioningly. The consequence, as in most symposia, is a highly uneven performance. Douglass North polishes off the industrialization of the United States in 32 pages, and offers a bibliography of 2½ pages. Landes writes an essay on technological change and development in Europe, 1750-1914 (right time, right place), but covers a myriad of topics beyond the relationship of technology to development and spins out 330 pages and 63 pages of bibliography. At the same time, if the substantive-importance-per-page ratio be computed, it is Alexander Gerschenkron who patrols the opposite boundary from North, with his 93 pages plus 3½ pages of bibliography, on whether the emancipation of the serfs in 1861 was or was not a contribution to the industrialization of Russia.

This is, by and large, the old economic history. There are two meanings given to the new economic history, one, that it uses econometrics, and the other that it is concerned with the testing, however primitively, of economic theories, and especially, over the long period, theories of economic development. This work is excluded more from the former than the latter. The first essay, by W. A. Cole and Phyllis Deane, produces a Kuznets-type survey of

the Growth of National Income in the world, but there is only a handful of tables, and the emphasis is on description, rather than measurement. Elsewhere in the testing of theories the views of Gerschenkron on backwardness, H. J. Habakkuk on the impact of factor prices on technological change, Albert Hirschman on linkages, Innis on staples, W. A. Lewis (or Mark) on growth with unlimited supplies of labor, W. W. Rostow on stages, and Schumpeter on entrepreneurship all come in for attention but it is rarely systematic.

As the old economic history, most of it is very good indeed. G. C. Allen's essay on the industrialization of the Far East is concise on Japan, if perfunctory on China, India, and South-East Asia. Largely descriptive, it emphasizes the contrast among the Japanese (imitative), Chinese (scornful), and Indian (passive) responses to Western industrial penetration. Equally descriptive are Glass and Grebenik in their essay on world population, which offers little or no demographic explanation, but compresses much fact into small space; Youngson on the opening up of new territories, who, however, organizes much of his material about an implicit Innis model of the differing significance for settlement and development of different staple commodities; Girard on transport; and Portal on the industrialization of Russia. The Girard piece is a brilliant example of the old economic history with the interesting generalization that new forms of transport—toll roads, canals, steamships, railroads, airplanes—start out as complements to the existing major forms, gain efficiency and compete on a wide front, succeed in substituting, but finally as quasi-monopolists raise prices to the point where still newer forms of transport are encouraged. (This may be old economic history, but it contrasts favorably with some of the new in which cost functions for competing forms of transport are *assumed* to be infinitely elastic, from which it follows, after a formidable analytical exercise, that the railroads had no impact on the economic development of the United States. Where competing activities have constant costs, any one of them is redundant—by assumption.) Girard's essay is also studded with sweeping generalizations of the sort that the design of a transport network may be unrelated to economic activity, but its maintenance is so related; that the transcontinental railroad altered the world political balance, which until then had favored thalassocracies; that cheap transport by making the masses mobile made democratic civilization possible.

North apparently did not take his assignment seriously. There is some analysis of declining transport costs and merging of markets, forward and backward linkages, economies of scale in a given process which led to disintegration (owing of course to diseconomies of scale in administration which are not mentioned). Some of the analysis of comparative advantage and location theory is either wrong or badly expressed. On the whole, however, he is content to offer a pedestrian account, of which an extreme sample can be culled from page 697:

Iron and steel played a prominent part in the manufacturing development of the American economy during this period. The major technological developments were the Bessemer and the Open Hearth processes. These were followed by a whole host of innovations, in bigger and better blast furnaces, improved rolling mills, and a vast array of new techniques which increased

the size and efficiency of the steel industry and made steel a substitute for almost all the uses which iron had previously served.

While it is an outstanding example of tepid prose and lame analysis, it is a little unfair to pick this passage which may have been intended to serve as a summary introduction to what followed. North's predilection for quasi-quantitative words in this essay, however, is illustrated by his repeated use of the word "important" which occurs four times each on pages 684, 685, and 689, and six times on page 687.

The editors admit, or possibly even boast, that there is no necessary agreement among the contributors. This is illustrated effectively in the Lewis model of growth, and the extent to which the industrialization process depended upon a steady supply of labor from the farm. Landes states that the Lewis model is applicable to Britain only with major modifications (p. 346n.). In his careful discussion of European agriculture Döring focuses on population, adopting the Lewis view that retention of surplus labor on the farm harms both industry and agriculture. In contrast to the recent views of T. W. Schultz and others, he believes in disguised unemployment, and suggests that growth in agricultural productivity through investment must wait on its removal. Portal starts out his essay with a half-sentence exactly contrary to what Gerschenkron has taken broadly 100 pages to disprove, though he later modifies this in Gerschenkron's direction (pp. 810-12). The half-sentence asserts that the industrial revolution in cotton textiles in Russia "was conditioned by the emancipation of the serfs, which facilitated the recruitment of a labour force by freeing the peasant masses and making them more mobile" (p. 801). Gerschenkron demonstrates conclusively that the issue was much more complex (cf. Evans' law that everything is more complex than most people think), and that serfdom was replaced by other links to bind the peasant to his village—undivided rights in village communal property, undivided obligations to pay for the land to the gentry or the state, and passport control. He explores the economic, social, and legal status of the peasants at length and concludes that Russian industrialization did not depend upon a flow of peasant labor but involved labor-saving investment instead—a substitute for what is usually called a prerequisite.

But the most interesting, challenging, provocative essay in the volume is Landes' sprawling discussion of technological change in Western Europe. His mastery of technical process, demonstrated in a dozen industries in half as many countries, is dazzling at the micro-level, and the descriptive passages, which make up two-thirds of his book-within-a-book, are must reading for student and scholar. When it comes to explaining why things have happened the way they have; why Britain pioneered in the Industrial Revolution and the Continent lagged in emulation; why the hand-loom weavers and the nailers survived after the development of the factory, why Britain fell behind after 1870, and it was Germany which overtook and surpassed her in technological achievements, he is not quite so satisfactory. Partly it is a question of the organization of the essay, which has difficulty in making up its mind whether to proceed on chronological, geographical, or analytical lines. Partly

it is a woods-and-trees problem. Partly, this reader believes, he underestimates the power of the Lewis model and what happens to profits when wages start to rise; and that of the Salter model, where old methods can survive so long as total average costs on the new process are greater than marginal costs on the old.

But Landes caps his brilliant virtuoso performance in the description of technology with the right answers. He has moderated his earlier insistence on the primacy of the entrepreneur, though the latter continues to play an important part. He eschews all single-valued explanation. In dealing with the loss of British leadership, for example, he puts aside resources, population, and overseas investment, and whilst skeptical of the advantages of backwardness, focuses on the handicap of the headstart—interrelatedness, the flagging of entrepreneurial energy, the weakness of education and science. Economic history is good only for middle-range conclusions. Economic development by and large is too complex.

Unlike the curate's egg, this book is decomposable, but like it, parts of it are very good indeed.

The index suffers from omission of all references to cited literature. The 100-page bibliography, largely Landes' 63 pages, is superb.

C. P. KINDLEBERGER

Massachusetts Institute of Technology

The Roots of American Economic Growth, 1607-1861: An Essay in Social Causation. By STUART BRUCHEY. New York and Evanston: Harper & Row, 1965. Pp. xiii, 234. \$4.95.

The express purpose of this slender volume is to trace "the historical emergence of [industrialism's] necessary and sufficient conditions in the United States. What aided and what inhibited the emergence of those conditions? In what attitudes and values, institutions, processes and events, did they have their roots?" (p. 13). In a discursive, engagingly written commentary on aspects of the economic, social, and political history of the American colonies and the young nation, Stuart Bruchey sifts the earth already turned by others, rather than reporting on fresh digging into primary sources. *The Roots of American Economic Growth* is intended to provide an interpretive guide to the recent literature and, above all, an interdisciplinary synthesis that will "place the process of economic growth within the mainstream of American history" (p. xi.). In interdisciplinary matters the author appears to be of the total immersionist persuasion, and the subject of this baptismal exercise emerges lamentably waterlogged.

Taken one at a time, many of the resumés of the literature provided by the book are quite useful, and, all in all, the state of knowledge remains in much the same condition as that in which Mr. Bruchey found it—comparatively few new confusions are introduced. Students, however, should be particularly alerted to steer clear of the sections dealing with international trade and finance, which is rather a drawback when one considers the openness of the economy under discussion. The following extract (p. 142) may stand as a warning:

Americans also tapped foreign savings by selling goods and services abroad, and while resultant earnings financed the importation of some capital equipment, one main contribution to domestic capital formation was indirect. During three periods in the antebellum years, namely 1793-1807, 1815-18 and 1832-39, the terms of trade on which American exports were exchanged for imports of consumer goods were favorable to the United States. That is to say, a greater rise in export than in import prices permitted a given quantity of American goods to command a larger quantity of foreign goods. By buying abroad instead of at home Americans thus saved money, and the savings could be released for domestic capital formation.

The preface discloses that the author is, by training and inclination, a social historian; he modestly avers economics is not really his forte. Thus disarmed, the reviewer must follow Bruchey in being more concerned with the grand design than with details of its execution.

"Community will and acts of governments, the structure of society and its values, knowledge and education, attitudes toward technological change, the actions of private investors, and the effects of widening markets"—in these are found the roots of industrial development and America's economic growth (p. 208). The thesis of the book is that the acceleration of per capita output growth during the first half of the nineteenth century resulted from manifold complex interactions among economic and noneconomic changes. Bruchey is enough of an economist to posit that within the foregoing set everything must have depended upon everything else, in at least two different ways. Widening markets encouraged specialization and paved the way for technological advance; specialization combined with education to foster occupational differentiation, which, in turn, increased social mobility. Greater social mobility intensified the vigor with which Americans pursued material gain, thereby increasing their receptivity to technological innovation and the responsiveness of private investors to opportunities created by widening markets. "Heightened alertness to the possibility of material betterment," a by-product of greater social mobility, also led communities to prod governments into actions which improved transportation, expanded markets, encouraged private investment, and furthered mass education. Education, as we already know, raised productivity and increased social mobility. And so on. As far as one can tell, these processes occurred simultaneously, at unspecified speeds, each leading to highly significant changes of unknown magnitude, all of which contributed to growth.

Bruchey turns this wonderful Chinese puzzle over and over, peering at it from all angles, marveling at the way it fits together, and ultimately decides it has no key pieces and is not meant to be taken apart. At one or two points in the book he is sorely tempted by the thought that the whole thing may have hinged upon the "progressive permeation" of the "desire for efficiency in the use of economic resources"; this "wide diffusion of the demand for growth" increased individual motivation and projected the federal government into "a place of central importance in American growth, because of its contribution to the formation of a national market and the national credit" (pp. 208-9, 213). But such impulses to stress the sociopolitical (or, indeed, any) parts of the

process as having been more consequential than others are firmly controlled. The result is a "balanced" appraisal, in which all the pieces are seen to have formed an historically necessary and obviously sufficient whole.

So jejune a rendering of American economic history will come as a disappointment for readers who do not quickly get the message telegraphed by the methodological discussion in Chapter I: "To force a translation of qualitative factors into the language of numbers is to guide us to reality in the way of parody. To apply formal economic analysis to the complexities of long-run change is to invite the rigor of *rigor mortis*" (p. 10). It is not simply a matter of the prevailing irrational passion for dispassionate calculation having taken all the joy out of writing economic history. The problem goes deeper, for "quantomania" and narrow adherence to economic logic may choke off discussion of the sociopolitical contributions to American economic growth, although their importance is, for the author, clearly demonstrable by the exercise of "historical judgment." The proposed cure for this real ailment is no mere antidote for a bad case of the "new economic history." It is also a powerful specific for cramps caused by reliance upon evidence and connected argument.

Take the treatment of the role of vertical social mobility as a case in point. Bruchey asserts that the increasing fluidity of the American social structure accelerated the pace of per capita output growth by raising "incentives to produce." Yet he can grant there is presently no evidence that the structure of society had become more (or less) rigid between, say, the mid-eighteenth and the mid-nineteenth century. Nor does it seem necessary to define social "incentives to produce" in a way that would distinguish them from economic incentives, or permit identification of changes in the degree of "social motivation." When one comes right down to it, the author barely offers an explanation for the putative functional connection between the time derivatives of these two state variables. The whole idea seems to derive (pp. 201-2) from de Tocqueville's comparative observation that in America, where differences in social status were confined mainly to those deriving immediately from differences in wealth, inferiority of economic position became an overriding preoccupation; immense energy was poured into attaining material "equality" with others. This insight is surely too slender a reed to carry the weight of even a partial explanation for the upward shift in the long term rate of U.S. per capita output growth. Moreover, it bends easily in quite different directions. Might one not infer from de Tocqueville's comment that in the American setting the proximate governor of individual economic vigor was the perceived degree of inequality in wealth? Then, more pronounced inequality in the distribution of wealth (or income)—which, by the way, Bruchey would equate with greater *rigidity* of the social structure (pp. 59-60)—should have led to still more ardent dollar-chasing.

In an appreciative blurb on the dust-jacket of this book, Thomas Cochran says: "I think it will be widely accepted as the standard interpretation of the first phase of American Industrialism." One must trust that this was just an idle threat.

P. A. DAVID

International Aid—A Discussion of the Flow of Public Resources from Rich to Poor Countries with Particular Reference to British Policy. By I. M. D. LITTLE and J. M. CLIFFORD. New York: Aldine, 1966 and London: George Allen and Unwin, Ltd., 1965. Pp. 360. \$7.50, paper \$2.95; 45s, paper 25s.

If, in the outpouring of development literature, any branch of the subject can possibly have been underwritten, it has been foreign aid. Memoirs of aid administrators, governmental reports, and much economic journalism on the subject exist; but the comprehensive and systematic type of study that would appeal to professional economists has been surprisingly rare. This book is therefore to be welcomed—and it is to be lauded for its excellence in sorting out the principles of aid-giving and for its lucidity in analyzing the complex interrelationships between donors' and recipients' problems within the framework of development planning.

While comprehensive, the argument never bogs down in secondary detail; while rigorous, the analysis never becomes overly formal or unnecessarily technical; and while grounded on fundamental economic principles, there is still much of the needed contact with the tradition of political economy. It is readily admitted that almost all aid decisions require political judgment, both as regards the donor's political interest, and as regards the influence of political factors on how effective a particular act of aid-giving will be in promoting development. But granting this, the authors still have much to contribute on the parallel economic judgment that is necessary to get the best particular decisions made.

The book is divided into four Parts. The first traces the history of aid (unfortunately, this makes for a rather dull and slow start); the second concentrates on problems of aid recipients (here are some of the most incisive analytical sections); the third examines donors' problems; and the last part largely applies what has been said in earlier chapters to current and future British aid policy (but many of the observations would also apply to U.S. aid policy).

The vagaries of their subject notwithstanding, the authors state their conclusions forthrightly and unambiguously. On the capacity of poor countries to use aid, they conclude that, over the next few years, around \$1-\$1½ billion more public aid could be applied with considerable effect, mostly in India. But, for many recipients, improvements in the conditions and forms of aid might do more to raise the rate of development than an increase in the volume of aid. They further believe that the political impact of aid could be improved if Western donors would concentrate more on economic development, and worry less about the effects on their own economies and trade, and less about their own political aims. Aid-tying is strongly criticized: it distorts investment priorities and twists the import pattern in favor of capital goods, resulting in an underutilization of domestic resources and a less effective use of aid for economic development. For balance of payments reasons, U.S. and British aid cannot be untied completely, but it is submitted that in giving aid the donor should be prepared to pay such proportion of the domestic costs as is appropriate to the nature of the project, or maintain a policy of donor-or-local (or, even better, donor-or-developing-country) procurement; or, in countries

like India, where it can reasonably limit its project aid to import costs, it should give an adequately large proportion of general balance-of-payments aid. (It can, however, be questioned whether aid-tying has really been of substantial help to the U.S. balance of payments.) To ease the problem of aid-tying, the authors join those who advocate an increase in world liquidity and the channelling of newly created international credit to the poor countries (as is proposed in the Stamp Plan). To allow greater attention to the economics of aid usage, there should also be closer coordination among donors in the field. Lastly, on the financial terms of aid, the authors conclude that, in the case of almost all donors, repayment terms are still far too short to be appropriate for development aid. "Donors as a whole cannot seriously expect to be receiving resources back from the present recipients in this century. With few if any exceptions, if a single donor gets paid back it will be from the aid of others. Interest payments also serve no function in aid to governments. Logically, all such aid should be grant-aid. Although we do not, in fact, advocate this, we do suggest that all development aid should be in the form of very long-term loans at merely nominal rates of interest" (pp. 335-36).

The real merit of the book, however, does not lie in its (essentially unsurprising) conclusions—but rather in the fact that the authors sharpen a number of critical and confusing issues on their way to reaching these conclusions. On page after page, the reader is offered an abundance of good sense on such issues as what is the true cost of aid; whether aid is needed for balance of payments' reasons quite distinct from the need for aid as an adjunct to savings; the relation of aid to trade, and the extent to which they are substitutes or complements; whether any burden-sharing formula is feasible; how aid should be used to maximize the present value of the increases in consumption per head (the general principle of maximizing utility, of which maximizing development is a borderline case); whether aid should be given on a project or plan basis; how to meet the "home cost" problem; how to limit the abuses of private export-credits; whether a reasonable quantitative estimate of the need for aid can be produced; and how to ameliorate the debt-servicing problem by tailoring the terms of aid to suit the respective recipient.

In sum, a substantial and thought-provoking study that merits wide attention—especially at the present time when the capacity to utilize aid more effectively has risen in many poor countries, but the real value of aid has declined to a distressingly low level.

GERALD M. MEIER

Stanford University

Canada: An Appraisal of Its Needs and Resources. By GEORGE WILSON, SCOTT GORDON, STANISLAW JUDEK, and ALBERT BRETON. New York: Twentieth Century Fund, 1965. Pp. lxx, 453. \$7.50.

This study is a stepsister to the other volumes in the Twentieth Century Fund's *Needs and Resources* series. It differs quite remarkably from the others both in omission and commission. The main statistical work in the Canadian study is on basic trends in the broad aggregates of economic and social development. This statistical material is fully integrable with the data for other volumes of the series. However, on many subjects, the statistical treat-

ment in the study is much less detailed than in the other studies. Separate chapters are not included on each of a large number of classes of consumer requirements; there is very little on urban development and redevelopment, housing, or the composition of government expenditure. The novel elements of the Canadian study are the analytical and evaluative texts and the forays in political economy. Some applications are made of theories of economic growth to explanation and forecasting of Canada's performance. Some analysis is made of Canada's migration experience and policies, of the changing structure of social power and of the fundamental political and social drives of the nation. Also the book contains much more evaluation of ideas, performance and policies than did the other volumes. The authors are quite outspoken, for example, on Canada's tariff policies, the issues of foreign (mainly U.S.) ownership and control of resources and activities in Canada, the country's postwar developmental policies, and the role of Canadian policy as a cause of Canada's relative economic stagnation between 1957 and 1962.

To a reader in the United States, two political strains in the book will be startling and yet among the most valuable features. The first is the impact of "the French fact." The superficial aspect is in the appearance of both English and French-language texts for several sections and a French version only of the Commentary by Albert Breton. The more important aspect is on the French "facts" in the creation of the nation in the first place—and as major forces in the current reshaping of the nation. The other feature which may startle the U.S. reader is the (now nearly two-centuries-old) concern over the challenge to Canada's independence from the United States. The forms of the challenge have changed. Nowadays one hears an astonishing amount of talk in Canada about U.S. economic and social imperialism. These two political strains are brought together in the introduction: "There is a continuing uncertainty and irresolution about Canadian nationhood . . . for there are subtle and abiding strains upon it. . . . These strains spring from two sources . . . the internal cleavage between French and English, and the external proximity of the United States . . . and both of these are as powerful today as they were in 1867" (the birthday of Canada's confederation). Breton's commentary somewhat discounts the difficulties of the French "facts" for the viability of the nation, and rightly so in my view. And the main authors discount the U.S. imperialism line considerably, also rightly so in my view. But these two forces are among the most prominent ones still shaping Canada's economic prospects.

The book begins with a long introductory essay on *A Nation Still in the Making*. This is an interpretation of the forces which brought Canada into being as a nation; and of the success of the railroad building, the partial success of the migration policies and the failure of Canada's tariff—the three elements of the historic National Economic Policy. More recent trends and issues are also reviewed. Part One, *The Recent Past*, consists of four chapters looking back on Canada's economic experience, mainly during the last 30 years. Chapter 1, *Dimensions of Growth*, analyzes the usual data on the national economic aggregates, and general indicators of structural change; data on changes in income distribution are also presented. Chapter 2 is on Population

Patterns, the one rather unique feature being the presentation of some detail on immigration and emigration. Chapter 3 is on Regional Differences in economic performance, history and structure within the country, a long-standing concern in Canadian life and policies. Chapter 4 is on the Foreign Influence. Canada's trading relationships and trends are analyzed, as well as the various indicators of foreign indebtedness and uses of foreign financing.

Part Two is on Resources. Chapter 5, on Land and Natural Resources, presents a very optimistic view of unutilized potentials in Canada's position in nearly every respect—agricultural land, minerals, forests, urban sites, etc. Chapter 6, on the Labor Force, is fairly routine, except for the analysis of external migration as a factor in the size and composition of the labor force. Chapter 7, Capital, presents data on the capital stock, and estimates of both average and marginal capital-output ratios. Saving and investment relations are also analyzed. Chapter 8, on Management, Productivity, and Research is somewhat unique in analyzing the supply of management, in presenting a view (commonly referred to in Canada as the WASP theory) of the structure of the power elite in the country, and in some attempt at analysis of data on research and development expenditures. The discussions of productivity are more routine, various forms of gross measures being produced as well as some discussion of productivity differences among various sectors of the economy and differential productivity trends. The WASP theory of the power elite attempts to show (and then to analyze) the extremely heavy weighting of White Anglo-Saxon Protestants in what is identified as the commanding heights of business, political, and institutional power.

Part Three, The Future, contains projections to 1970 and 1975, essentially as a simplified general exercise in economic forecasting, not using advanced techniques or conceptual framework. Projections are made for population, labor force, unemployment, productivity increase (in the sense of output per man-year employed), and a few broad categories of expenditure. The more elementary cross-checks for internal consistency and plausibility are made. The book concludes with an Epilogue, which brings the trends, economic analysis, and projections into relationship with the political and social problems; and Breton's Commentary. The Director of the Fund describes the latter as "themes in the study which might have special interest for the French-speaking community in Canada." Breton has certainly not limited himself to this task, or even made it his central concern. He has made comments on the French-English issues, which are at least as interesting to the English-language groups in Canada as to the French. More importantly, he has offered important qualifications to the general content of the study, of interest to all readers—comments, for example, on interpreting the productivity trends, on the analysis of changes in income distribution, on the processes of adaptation in the country, on neglect of money and finance in the book and so on. It is indeed a pity that this commentary was not translated into English.

The book is quite a mixed bag. There are exciting insights, such as the hypothesis of inferiority of Canada's management talents because of the preeminence of the WASPs in the power elite; the themes of missed opportunities of economic maturity and increased productivity in the postwar world; and the

analysis of brain "gains" and "drains" in the country's external migration. But there are pieces that are thoroughly pedestrian, such as much of the demographic analysis and the discussion of labor force participation. The modernized "export staple" theory of Canadian economic growth is not really convincing, nor is the analysis of Canada-United States differentials in capital-output ratios. While I share the authors' doubts about the usefulness of Canada's tariff, the treatment of the tariff in the book is rather weak, relying on older and somewhat discredited estimates and concepts of the effects of Canada's commercial policy. One gets little treatment in the book of the important issues of major business cycles and growth cycles, the neglect of both of which limited the effectiveness of the Gordon Royal Commission a decade earlier. On economic policy the book is a mixture too of extremely perceptive analysis, for example of migration policy and of some incidents of fiscal and monetary analysis; and of disappointments, for example regarding the role of the post-war structure of taxation as a factor in the country's economic performance. Nevertheless the study is a very useful one indeed, both because much of the economic description and analysis is excellent and because of the attempt to integrate political and social considerations with the more narrowly economic ones.

DAVID W. SLATER

*Queen's University
Kingston, Canada*

The Political Economy of Latin America. By WENDELL C. GORDON. New York: Columbia University Press, 1965. Pp. x, 401. \$8.75.

Although the author writes in his preface that the "royalties for this book have been waived so that it can reach the greatest number of students," the price still precludes its use as a supplementary text in the classroom. This is unfortunate, because the commentary on the need for institutional change will receive substantial support from regional specialists. The book begins with a brief discussion of institutional theory (à la C. E. Ayres) and then outlines the evolution of Latin American economic systems. The historical introduction is interesting, but needs elaboration in order to promote genuine understanding of relevant issues. The author's tendency to oversimplify complex problems in a rather naïve fashion is demonstrated when he suggests that perhaps the United States should promote a policy whereby "no member of the United Nations . . . will diplomatically recognize any but a democratically elected government in the future" (p. 35).

Part II consists of five chapters dealing with various aspects of market organization, e.g., private practices, government regulation, commodity control schemes, etc. The complicated legal arrangements for carrying on business activities in Latin America are discussed, while sharp criticisms are leveled at certain prevailing practices. Professor Gordon is unhappy with the lack of competition in industry, the excessive use of price controls, and the problems associated with commodity control arrangements. Concerning the latter, his propensity to rely on normative analysis is evident when he describes the Organization of Petroleum Exporting Countries as a "conspiracy against the gasoline

buyers of the world . . ." (p. 89). Under the caption of Welfare, Part III traces the labor movement in the region, social security legislation (which, it is alleged, has been enforced only against foreign-owned companies), and the level of living, income, and production. Some readers will be troubled when they read that "the mythology of free private enterprise is that profits are a reward for risk taking, or innovation, . . . or something of the sort" (p. 98), or that "the conclusion should not be drawn that Latin America is relatively more socialistic than is the United States" (p. 99). These statements may be true, but they are not supported empirically in this volume.

Part IV, Economic Development, makes up the core of the book with eight chapters devoted to such topics as the basis for industrialization, planning, capital formation, priorities, etc. Although some of the descriptive remarks are provocative, the experienced development-oriented economist will encounter little original analysis. Gordon argues that "the accumulation of technical knowledge is the great dynamic force in economic progress [and] that the chief . . . planning problem is to create the institutional conditions which will permit technical knowledge to be assimilated" (pp. 159-60). The alleged institutional barriers that must be dealt with include landowners (or the oligarchy?), dictators, the army, the Church, the public bureaucracy, and the Spanish language itself. In short, the formidable list essentially covers the major existing institutional characteristics of the region. It is obviously not suggested that they should be abolished, but the necessity for near-term modification is urged—man should be the master, not the slave of his institutional environment.

On the subject of planning, Gordon's pen is particularly sharp when he criticizes the common practice of using foreign advisory personnel to construct an ambitious plan, and then leave the all important implementation to local politicians after the draftsmen have departed. Rather than an unrealistic emphasis on ten-year development plans, it is suggested that the real need in Latin America is for "unprogrammed planning" that would be directed toward more effective mobilization of the "least effectively used" resource, namely, underemployed manpower. Also, industry studies would help mitigate the thorny complementarity question of which country or region should develop a particular industry. The Alliance for Progress is validly criticized for its failure to grapple with this by placing undue emphasis on national plans for self-sufficiency, even though the desirability for increased regional integration is recognized.

Gordon believes that a shortage of domestic saving has not been a major factor in holding back Latin American development. He rejects the notion that monetary savings must precede investment (an argument used to defend skewed income distribution and to attack progressive taxation) and suggests that a government can create the funds needed for capital formation if a scarcity of voluntary, private savings is evident. This is the familiar inflationary route to development and has merit if unemployed real resources are in fact available, and the new investment projects do not place excessive strain on foreign exchange availabilities. Historical experience, however, indicates that Latin American governments have had difficulty in exercising adequate self-

discipline in their monetary and fiscal policies. Foreign investment as a development vehicle is recognized for its potential in transferring technology, but the impression that the developed countries have made a significant resource contribution to Latin America between 1946-61 is rejected. "Net capital inflow . . . was \$11.8 billion and net debt service transferred out was \$16.0 billion for the period . . ." (p. 240). Developmental priorities are examined with a critical appraisal of the usual conspicuous production (i.e., steel-mill) approach to government planning. It is argued that the entire region should be developed in terms of six or eight major industrial complexes. Many economists would agree with this recommendation, but political realities make meaningful implementation unlikely.

Part V, Trade and Finance, contains chapters on trade patterns, common markets, monetary standards, banking and public finance. A strong point is made in support of improving the qualitative ("how it is used") aspect of credit control. Indeed, traditional lending practices leave much to be desired, but it may be difficult to accept the remark that "there is in general in Latin America no shortage of money and credit in terms of total quantity" (p. 348).

In conclusion, the reviewer appreciates the author's statement that "this book is much more of an expression of opinion than it is a rigorous report of research findings" (p. 387). The book is too impressionistic, negative, and sweeping in coverage. The lack of scholarly documentation will disappoint many students, but the writing style is lively and designed to have an emotional impact. The shortcomings would have been minimized, however, if the author had devoted greater attention to prescription for remedial policy action.

Parsons College

Statistical Methods; Econometrics; Social Accounting

Studies in Mathematical and Managerial Economics. Vol. I, Optimal Decision Rules for Government and Industry. By HENRI THEIL, in association with others. Chicago: Rand McNally & Co., 1964. Pp. xvii, 364.

In this book Henri Theil presents a statistical decision analysis, and gives example applications to a number of concrete decision problems drawn from the economic histories of the United States and the Netherlands, and drawn from the production and employment problems faced by a particular business firm. The reader is led successively through the development of the theory from the simpler static case under certainty to the fully dynamic case under uncertainty. The theory developments are followed immediately by concrete examples. Both the technical developments and the applications are discussed fully and in detail, and the exposition attains a high level of clarity. This book should be an important contribution to those who are interested in quantitative decision-making in business, government, and elsewhere. In addition it should help to clarify many fundamental points in economic theory relating to decision-making.

Perhaps the best way to indicate the range and depth of this book is to discuss in some detail one of Theil's more advanced examples. He considers the

problem of making decisions on national economic policy for the Netherlands for the period 1957 through 1959. The policy instruments are taken to be the general wage level, three tax rates, and the level of government expenditures on commodities. National economic welfare is assumed to depend quantitatively on the level of unemployment, the change in the level of prices in private consumption, the share of wages in national income, and the surplus in the balance of payments. In addition, welfare weight is assumed to attach directly to the above instruments of policy which the government uses.

The welfare weight which attaches to the above variables is assumed to differ somewhat for different interest groups. Specifically three sets of preferences are formulated, one for each of the following: labor, employers, and a neutral group that is intended to represent the broad national interest. The problem posed by Theil is to find the decision strategy that, looking forward over a three-year planning horizon, will achieve an optimal compromise over the various objectives and interest groups in setting the four instruments of policy, taking into account the fact that uncertain disturbances also will have impacts on the economy. The conditional forecasts that are needed for this decision analysis are based on a 40-equation econometric model of the Dutch economy. Theil makes a thorough exposition of this problem including such subtleties as penalizing erratic fluctuations of the instrument variables and carrying over unfulfilled objectives to succeeding years.

He then proceeds to solve the problem. This is done by approximating the welfare functions by quadratic equations and maximizing the expected values of welfare subject to the constraints imposed by a linear econometric model of the economy. The political compromise between the conflicting interest groups is attained by putting equal weight on the welfare loss that each group suffers from being forced to compromise its ideal plan for running the country and then finding the compromise that minimizes the total loss.

Not only does Theil treat the problem of finding the optimum strategy for making the decisions, but he also considers: (1) the welfare cost of the government's inability to forecast with perfect accuracy the 13 exogenous variables that the government does not control, such as exports, (2) the consequences in terms of welfare loss of making errors in estimating the parameters of the econometric model, and (3) the welfare cost of errors in estimating the parameters of the welfare functions. He studies the rate at which the cost of forecast errors declines as the forecast span increases. By using the econometric model and the optimum strategy, forecasts are made of future actions and the corresponding future outcomes. He considers the effect of truncating the planning horizon to three years or extending it to an infinite horizon. He considers the extent to which some policy instruments are substitutes for others and the extent to which they are complements.

Although one can quite rightly question the rather severe restrictions imposed by a symmetric quadratic utility function and by a linear econometric model, this linear decision rule analysis has the great virtue that its solution is sufficiently easy through matrix manipulations to enable quite subtle and profound questions to be studied directly. Hence the power of this approach should not be underestimated, particularly as a first approximation.

Each section of the book contains a clear nontechnical summary at the end,

and many readers will find this a useful way to start the section. A similar remark might be made about the theory and applications chapters. Many readers will find it easier to read the theory chapter after having first examined a concrete application. The availability of the nontechnical summaries and the clear separation of the theory from the applications mean that readers unfamiliar with matrix algebra can still obtain a great deal from this book.

Now for more technical points.

The matrices arising from practical problems may readily become too large for hand computation, and the reader looks in vain for Theil to mention the availability of a computer program¹ that might perform the mathematical manipulations of the decision analysis.

On page 123 Theil lays considerable stress on the important fact that a decision strategy for the sequential uncertainty case should take into account the fact that new information will become available before subsequent decisions are made. He shows a case in which the mere knowledge that information will be available influences the action that is taken in the initial period. In strong contrast to this, however, he demonstrates that the same linear decision rule serves for decision-making under certainty, for making simultaneous decisions for many time periods under uncertainty, and as the optimum strategy for making the first decision in a sequential uncertainty situation. Thus Theil has given concrete examples of two cases, one in which the strategy approach makes an important difference, and one in which it does not. This suggests that there are two classes of mathematical decision models, one of which is vastly simpler since it does not require formal treatment of the strategy problems in the solution process. The property of certainty equivalence is undoubtedly very special, perhaps being limited to the linear decision rule case, but there may be a larger class of decision models in which the strategy problem may be treated implicitly rather than explicitly in the solution process.

Because of the relatively small amount of work that has been done in quantitatively estimating social welfare functions, and also because of their somewhat intangible nature, it comes as good news that Theil finds on page 84 that the errors from misestimating the parameters of the welfare function are much less serious than those arising from errors in estimating the parameters of the econometric model itself.

Another encouraging note is the finding that forecast and other errors are less serious in their consequences for a dynamic sequence of decisions than for one-shot decisions. Even though the solution for an optimal strategy is usually more difficult to obtain, individual decisions are less critical because of the possibility of partially reversing mistakes in the periods that follow.

Theil's book is by all odds the best one to date in the exposition of the linear decision rule analysis and there is every reason to expect that it will make an important and lasting contribution to the introduction of such methods in government and industry.

CHARLES C. HOLT

¹ Of course, programs are readily available at most computing centers for all of the basic matrix manipulations that are involved.

Econometric Analysis for National Economic Planning. Edited by P. E. HART, G. MILLS, and J. K. WHITAKER. Proceedings of the Sixteenth Symposium of the Colston Research Society held in the University of Bristol April 6-9, 1964. London: Butterworths, 1964. Pp. xii, 320. \$14.50.

The Colston Research Society has held symposia and published papers annually since 1948 on diversified subjects including natural and social sciences and humanities. The main criterion for selecting a topic is that the subject should be at an interesting and active stage of development. The subject of the present volume easily meets the criterion.

Approximately eighty members participated in the 1964 symposium; most were from England, and a few from the rest of Europe and the United States. The papers included are J. J. Johnston, D. D. Bugg, and P. J. Lund, "Some Econometrics of Inflation in the United Kingdom"; J. D. Sargan, "Wages and Prices in the United Kingdom: A Study in Econometric Methodology"; Richard Stone, "British Economic Balances in 1970: A Trial Run on Rocket"; G. Pyatt, "A Production Functional Model"; L. R. Klein, "The Social Science Research Council Econometric Model of the United States"; P. J. Verdoorn and J. J. Post, "Capacity and Short-Term Multipliers"; A. Moustacchi, "The Interpretation of Shadow Prices in a Parametric Linear Economic Programme"; Leif Johansen, "Saving and Growth in Long-Term Programming Models"; W. Sadowski, "Economic Organization and Planning"; A. P. Barten, "Family Composition, Prices, and Expenditure Patterns"; and G. Menges and H. Diehl, "Time Stability of Structural Parameters." Each paper is followed by often interesting and instructive discussions.

To classify these papers into broad fields, four papers (Johnston, Stone, Klein, and Verdoorn) are on econometric applications, two papers (Sargan, Menges) on econometric methodology, two papers (Pyatt, Barten) on economic theory, and three papers (Moustacchi, Johansen, Sadowski) on programming. Although some papers (notably Sargan and Johansen) are of considerable theoretical interest, the main emphasis is on practice rather than on theory. Most authors impress me as having had much experience in econometric model-building or planning programs and being familiar with the complicated problems of the real world, and the hints and insights they throw here and there amidst formidable notation and lengthy mathematics must be very useful for practically minded econometricians or planners.

In this review I have chosen a few that have especially aroused my interest. I have not commented on papers by Stone and Klein on econometric models of the British and American economy, respectively, since each of them is a part of the greater program described elsewhere and had better be reviewed thoroughly as a whole. Stone's paper is related to the series of books, Department of Applied Economics, University of Cambridge, *A Programme for Growth* (London 1964), and Klein's paper to L. R. Klein, James S. Duesenberry, Gary Fromm, and Edwin Kuh (eds.), *The Brookings Quarterly Econometric Model of the United States* (Chicago 1965). Both papers are good introductions to the more detailed studies cited above.

The paper by Sargan is in a sense a sequence to his important work, "The

Maximum Likelihood Estimation of Economic Relationships with Autoregressive Residuals" (*Econometrica*, July 1961). However, it is self-contained and can be understood without reading the previous work. In the *Econometrica* article Sargan proposed a generalization of limited information, maximum likelihood estimator which is consistent and asymptotically efficient when the residual of the equation to be estimated follows a first-order autoregressive process. The spirit of the article was that, even if the real process may be more complicated, it is often better to assume at least first-order autoregressive process rather than complete serial independence for the residual. The present paper is written in the same spirit and solves some of the practical problems that arise in the use of the estimator proposed earlier.

The following is a summary of Sargan's paper. Let the regression equation be $y = X\beta + u$, $u = \rho u_{-1} + e$, where y is a vector, X a matrix of observed random variables, u a vector of unobservable random variables, e a vector independent and identically distributed random variables with mean zero and an unknown constant variance, and β is a vector of unknown parameters, ρ an unknown parameter. The subscript " -1 " means that each element of the vector is shifted one-period backward. Combining both equations, we have $y - \rho y_{-1} = X\beta + X_{-1}\beta\rho + e$, or simply $\xi a = e$.

1. If X is predetermined, estimate ρ and β by maximum likelihood, which is equivalent to minimizing $a' \xi' \xi a$ with respect to ρ and β . Test the hypothesis on the process of u by likelihood ratio test.

2. If X is partly endogenous, Sargan's *Econometrica* estimator may be used. Or use a 2SLS-type estimator which is asymptotically equivalent to the one used by Sargan and which is obtained by minimizing $a' \xi' Z(Z'Z)^{-1}Z'\xi a$ with respect to ρ and β , where Z is a matrix of properly chosen instrumental variables. Again the hypothesis on the process of u may be tested by likelihood ratio test.

3. Sargan compares the speed and efficiency of various iterative methods of solving the minimization problem described in (1) or (2). Since the minimum is a quadratic form, convergence to the absolute minimum is certain with probability one.

4. The asymptotic distribution of

$$\frac{\hat{e}'_{-1}\hat{e}}{\hat{e}'_{-1}\hat{e}_1}$$

is obtained, where $\hat{\cdot}$ indicates the estimate.

5. The estimator that takes into account first-order autoregression of the residual is compared with the one that assumes serial independence in estimation of some equations of Klein-Ball model, and they are shown to produce different policy implications.

Johansen's interesting paper analyzes the nature of solution of a finite period planning program with linear and nonlinear objective functions in a two-sector, vintage-capital model. In this review Johansen's conclusions are illustrated in a one-sector, no-vintage model.

A simplest finite-period planning program with a linear utility function may be formulated as: Maximize

$$\sum_{t=1}^T \lambda_t C_t$$

under constraints $C_t \geq C_t^*$, $I_T \geq I_T^*$, $Y_t = C_t + I_t$, $Y_t = \beta I_{t-1}$, $C_t \geq 0$, $I_t \geq 0$, where C_t is consumption, Y_t available stock, I_t input, and λ_t , C_t^* , I_t^* , I_0 are given constants. In this case it can be easily shown that the nature of the solution is I_1, I_2, \dots, I_k to be made maximal possible under constraints, and I_{k+1}, \dots, I_T minimal possible for some k between 0 and T . In other words, invest in the early part and consume in the later part of the plan.

From this we learn the following: (1) $C_t \geq C_t^*$ is necessary, for otherwise we may have $C_t = 0$ for some t . (2) $I_T \geq I_T^*$ is necessary, for otherwise $C_t = 0$ for $t \geq T$. (3) Solution varies greatly by a slight change in λ 's. To avoid this we must include more constraints on C 's.

In short, the use of a linear objective function makes a "programming plan" almost like a simple "target plan."

Johansen shows by means of admirable algebraic skill and perseverance that the same nature of solution as above holds also for a two-sector, vintage-capital model.

The use of a nonlinear utility function makes rigid constraints of consumption unnecessary, although the lower bound for the terminal capital stock must be still set. If we replace the linear maximand with a nonlinear

$$\sum_{t=1}^T \delta^t \log C_t$$

in the previous problem and omit the constraint $C_t \geq C_t^*$, the problem becomes: Maximize

$$\sum_{t=1}^T \delta^t \log C_t \quad \text{under} \quad \sum_{t=1}^T \beta^{T-t} C_t = \beta^{T-1} Y_1 - I_T^*,$$

where Y_1 and I_T^* are given constants, and it can be solved by the method of Lagrange multipliers. The solution is

$$(1 + \delta + \dots + \delta^{T-t}) C_t = Y_t - \frac{I_T^*}{\beta^{T-t}}, \quad t = 1, 2, \dots, T.$$

Johansen obtains the formal solution of a similar problem with a nonlinear maximand in a two-sector, vintage-capital model by means of Kuhn-Tucker theorem. The nature of the solution is analyzed by a thorough and ingenious intuitive inquiry and by a numerical example.

Pyatt argues that one should estimate the locus of *ex post* equilibrium points rather than the *ex ante* production function. The former may be linear, even when the latter is nonlinear. Here I shall illustrate it for the case of a Cobb-Douglas production function.

Let the production function be

$$(1) \quad X = \alpha N^{\beta} C^{1-\beta}$$

where X is output capacity, N is labor, C is investment expenditure divided by money wage rate, and α, β are constants, of which only α is assumed to change through time as a technology indicator. Defining $n = N/X$, $c = C/X$, we have from (1)

$$(2) \quad n^{\beta} = \frac{1}{\alpha} c^{\beta-1}$$

From (2) we have

$$(3) \quad n = \frac{\beta}{\beta-1} \frac{dn}{dc} \cdot c.$$

Thus, if $dn/dc = -r$ (r being the rate of interest) at equilibrium, we have

$$(4) \quad n = \frac{\beta}{1-\beta} r \cdot c,$$

which describes the locus of equilibrium points of n and c as α changes through time.

Pyatt seems to prefer, for reasons not clear to me, the production function,

$$(1)' \quad X = \frac{\beta}{\gamma} N + \frac{1}{\gamma} C(1 + \log \alpha + \log X - \log C),$$

where α, β, γ are constants, of which only α is assumed to change through time. For this production function, the equivalent of (4) is

$$(4)' \quad n = \frac{\gamma}{\beta} - \frac{1 + \beta r}{\beta} c.$$

His use of the Johansen-Kurz vintage-capital model as the general framework is only incidental as far as the main problem of the paper is concerned.

Verdoorn and Post discuss a 36-equation econometric model of the Netherlands' economy, estimated by the limited information, maximum likelihood estimator. The "unused capacity" variable is measured by the unemployment percentage \bar{w} , and it affects endogenous variables non-linearly, as the new variable is defined by $4.34 \Delta \log (\bar{w} + 2) - 0.2 \Delta \bar{w}$, which in turn affects variables linearly. The variables affected by the unused capacity are exports, export prices, investment, imports, wages, and employment. The short-term multipliers of the impulse variables (competing exports, autonomous expenditure, wage rate, import prices) upon endogenous variables are then calculated for various levels of the unused capacity variable.

There have been many econometric and noneconometric works that attempt to explain the cost-push or demand-pull nature of the postwar

British inflation. The paper by Johnston, *et al.*, presents a simple model that purports to explain the price change as a function of the ratio of the demand for consumption to the supply. Various variants of the model are compared on the basis of the mean-square error of the estimated prices in the sample period. The novelty lies in the estimation of the *ex ante* variable—the demand for consumption, which is an important step into a new interesting problem. Moustacchi discusses a linear programming model concerning the French Fifth Plan. Sadowski calls the reader's attention to a new and interesting problem of finding an optimal economic organization in planning. Barten considers the problem of measuring the effect of a change in the family composition upon the family expenditure. Menges and Diehl mention conventional methods of testing the hypothesis that samples come from the same population and apply some of them to testing a structural change of the parameters in a regression.

TAKESHI AMEMIYA

Stanford University

Systems of Social Accounts. By G. STUVEL. New York: Oxford University Press, 1965. Pp. xiv, 270, \$6.40.

This book by Professor Stuvél is primarily concerned with organizing and presenting economic data on the flow of goods and services as well as its counterflow of financial claims among various transactors by means of matrix accounting based on the so-called "double-entry" bookkeeping principle. Each transactor is accorded a row and the corresponding column in a square matrix and the entry in the *i*th row and the *j*th column represents the monetary value of the goods and services that flow from the *i*th transactor to the *j*th transactor or the counterflow of money from the *j*th transactor to the *i*th transactor. The basic scheme of matrix representation of economic data in this book is, therefore, identical to the one used in Leontief's input-output analysis.

Stuvél analyzes basically three types of problems in such matrix accounting: (i) methods of setting up transactors or *accounts* as well as consolidation and deconsolidation of transactors, (ii) relations between the *entries* in each cell of the matrix and the actual economic flows, and (iii) *measurement* problems which affect the amount of the entries. He demonstrates, by using the actual data of economic flows in the United Kingdom, how these problems may be partially solved.

The book consists of three parts which are further divided into 21 chapters. In Part I, "The Basic Accounting Framework," Stuvél starts by emphasizing the importance of representing economic data based on the double-entry bookkeeping principle. "They [identities in the double-entry system] ensure consistency between the values of different economic aggregates appearing in different parts of the macro-economic theory concerned" (p. 7). The basic two-account model which consists of the Production Account and the Financing Account is then introduced, which is next extended to include two sectors, the National Economy and the Rest of the World, each having Produc-

tion and Financing accounts. Finally, the Capital account is introduced to take care of the investment-savings aspect of economic flows. The last chapter in Part I discusses the valuation problem, introducing the Speculation account in the matrix presentation.

Part II, "Systems of Sector-Accounts," is essentially on the decomposition of accounts (discussed in Part I) into more detailed accounts in order to arrive at the "grand design of sectorized systems." For example, each of the Production, Income, and Capital accounts is further subdivided into Personnel, Corporate, and Government sectors. The Production account is decomposed into agriculture, manufacturing, and service; Capital account into various financial institutions. The nature of the transactions among these detailed transactors is explained in detail.

The last part, Part III, "The Flow Content of the Accounts," discusses various special problems that may arise in implementing the national matrix accounting. Such problems as the separation of the market economy and the subsistence economy, the problems in the measurement of fixed assets formation and consumption, the valuation basis, i.e., market price versus factor cost, factor income allocation, etc., are discussed together with miscellaneous definitional, measurement, and recording problems.

My major criticism is that Stuvell seems to have neglected a large body of theories and practices in business accounting which may very well be applied to the kinds of problems discussed in this book. Of course, there are differences between business accounting and national accounting but at the same time there are similarities between the two in many important aspects of the problem which he could have taken advantage of.

He states "In the national accounts double-entry reflects the fact that each transaction involves two different transactors, one of which will make a debit entry in his books in respect to the payable arising out of this transaction, while the other makes a credit entry in respect to the receivable that accrues to him as a result of the transaction concerned. In the business accounting, on the other hand, the double-entry principle refers to the two entries made in the book of one and the same transactor in respect to simultaneous changes in two items of his balance sheet" (p. 12). Although this latter statement on business accounting is true, it does not follow that accounting theories and practices in business accounting are, therefore, inapplicable to national accounting. Various issues on measurement and valuation that have been developed in business accounting may very well be made useful for national accounting, especially for those problems that are discussed in Part III. In addition, there are important branches of accounting which specialize in transactions among various segments of an organization, just as national accounting deals with transactions among various segments of a nation. Good examples are consolidation, home office-branch accounting, and other divisional accounting, etc. Cost accounting which traces the flow of goods from department to department can also provide a rich body of knowledge which may be translated into national accounting terms.

Furthermore, such translation immediately highlights the one-sidedness of national accounting presented in this book. In general, the commodity flow is

matched by the money flow in the opposite direction, but not always. Such a matching between the two flows requires the recognition of the cause-and-effect relationship between the two, which is difficult to do in some cases such as taxes, government subsidies, etc. Therefore, one cannot describe the economic flow by looking at the money flow only, as in the system presented in the book. Double-entry accounting is, of course, capable of handling both flows simultaneously as is already established in business accounting. Actually, the power of double-entry is that it forces us to trace the causal chains among various commodity and money flows and never to look at a flow independently from the rest of the flows.

Of course, the above comment is applicable to other articles in national accounting. However, I am disappointed because Stuvell's system is not different from the one that has been traditionally used in the input-output, interindustry analysis.

The main contribution of the book, therefore, seems to lie in the detailed discussions on the "sectoring," i.e., how accounts may be established and how transactions among accounts may be reflected in the matrix accounting. The book presents a well organized step-by-step approach to this problem of sectoring. In addition, Part III of the book provides a good discussion on important problems in the measurement and the valuation of economic flows that need to be solved. In this respect, this book will provide a good basis for understanding the ways in which national economic data may be organized, although, I must reluctantly add, the very limited number of references to related work in the field and the lack of bibliography isolate the book somewhat from the rest of the work in national accounting.

YUJI IJIRI

Economic Systems; Planning and Reform; Cooperation

Monopoly Capital—An Essay on the American Economic and Social Order.

By PAUL A. BARAN and PAUL M. SWEETZ. New York and London: Monthly Review Press, 1966. Pp. xiv, 402. \$8.75.

This book is worth reading; it deals with a vital area of economics, has a unique approach, is stimulating and well written. It represents the first serious attempt to extend Marx's model of competitive capitalism to the new conditions of monopoly capitalism. Even non-Marxists who read it will find some important additions to the economist's toolbox.

Paul Baran and Paul Sweezy begin with a long and careful analysis of price and profit decision-making under oligopoly conditions. They find that the modern large corporation still practices profit maximization, though over a longer time horizon and with *more* rational calculation than ever before. They find complete elimination of price competition, replaced by coordinated policies among firms (without need of any overt conspiracies). They further conclude that the degree of monopoly continues to increase, and that the increasing degree of monopoly—coupled with the astounding rise of productivity—has caused a very rapid increase in the "economic surplus."

This "surplus" is defined as "the difference between what a society produces and the costs of producing it." It is broader than the traditional concept "surplus value" (or profit, rent, and interest) because it also includes wasteful and nonproductive expenditures. The problem is the lack of effective demand to absorb the entire surplus. Basically, where Marx argued that competitive capitalism suffers cycles of boom and bust (but said "there are no permanent crises . . ."), Baran and Sweezy see monopoly producing a permanent tendency toward slowed growth and stagnation.

Some surplus is absorbed by capitalist consumption and investment, but they contend that both of these are relatively limited by the cautious outlook of oligopoly corporations with respect to dividends and new investment. Yet they believe that most surplus *is* absorbed, but by new institutional channels. They calculate the whole surplus in 1963 at 56.1 per cent of GNP. Of this total surplus, however, only 32 per cent was the traditional rent, interest, and profit (which must be offset by capitalist consumption or investment). Another 17 per cent of the surplus was spent on the "sales effort," in which they include a large part of all distribution costs, most advertising, most model and style changes, finance, insurance, real estate, and legal services. Finally, a huge 51 per cent of the surplus is absorbed by government spending, in which they include both warfare and welfare expenditures. The contention is that these latter elements of surplus absorption not only cut down on workers' consumption, but also on productive investment, so that they lower the rate of growth.

In spite of all these avenues of surplus absorption, however, they contend that all the potential surplus is still not absorbed, with the result that there is a certain amount of chronic unemployment. The question arises why government spending cannot absorb an unlimited surplus. They argue that private interests are no longer opposed to government spending per se, but will still oppose most nonmilitary spending, either because it competes with private enterprise, e.g., low-cost housing, or because it undermines class privileges, e.g., high-quality public education for all. Only government spending on highways is fully supported by big business, but this is already reaching a point greatly in excess of usefulness (since the auto is choking urban transport).

This leaves military spending, which does not conflict with private interests, but rather provides exceptionally high profit rates. Yet they argue that even military spending cannot be increased enough to provide peacetime full employment, in part because an increasing proportion goes into scarce research and engineering skills, and a decreasing proportion into mass production. Interestingly, the authors also argue—contrary to Hobson and Lenin—that foreign investment does *not* offer a vast area of surplus absorption. They point out that the profit and interest flow to the United States (earned by our huge "multi-national corporations") has been greater than the entire investment flow abroad.

They recognize that U.S. history since the Civil War (approximately the period of "monopoly capitalism") does not actually reveal such continuous unemployment nor stagnation. The model is accordingly modified to recognize the vast amounts of surplus absorbed at times by (a) wars and (b) major innovations (namely railroads and autos).

Having elaborated the economic model, they turn to its effects on society in the last three chapters. They argue that race prejudice has been an inevitable concomitant of the exploitation of the Negro under slavery and as the cheapest labor under monopoly capitalism. They also consider the effects on juvenile delinquency, divorce, and a whole range of expressions of pervasive alienation. Included are powerful essays on poverty, a long analysis of housing conditions, and a very detailed discussion of educational deficiencies.

Without detracting from the general importance of the book, some weak spots may be mentioned. First, the main point of the new "surplus" concept turns out to be the vast waste of social resources on war and war production. This could be handled conceptually as well, however, in terms of a deduction from Marx's surplus value; and could be more precisely calculated as a factor lowering the rate of growth within the terms of a Domar-type growth model. Secondly, the concept of "nonproductive" expenditures on "sales effort" and other capitalist "waste" is contrasted to a perfect socialist economy, but they neglect to contrast it to any actual socialist economy.

Third, how does the remaining *cyclical* unemployment relate to the long-run stagnation model of the monopoly stage? Fourth, granted that the degree of monopoly affects the distribution of the surplus among industries, by what mechanisms does it affect the *aggregate* surplus? Finally, their reasoning as to the limitations of military spending appears insufficient. Given the lack of political obstacles, it seems that *some* level of military spending will always create full employment (granted that it may be an absurdly high level, may lower the growth rate, and may tend to produce nuclear holocaust).

University of California, Riverside

The New Economics. By E. PREOBRAZHENSKY. Translated by BRIAN PEARCE, with an introduction by A. NOVE. Oxford: Clarendon Press, 1965. Pp. xx, 310. 55s.

This is a translation of a work which was originally published, first in article and then in book form, in the mid-1920's during the period when Stalin was consolidating his power and a great debate over the Soviet Union's economic course was raging. E. Preobrazhensky was the leading economic theorist of the Left Opposition and was subsequently executed in the purges of the 1930's. The book was of course suppressed in the Stalin era, and apparently neither it nor its author has been rehabilitated since. We owe its translation into English (a French translation has also just been published) at this time to the great increase in interest in problems of economic development which has been so marked a characteristic of the postwar period.

In choosing *The New Economics* for his title, Preobrazhensky was certainly not claiming to have discovered some brand new economic principles. He was an orthodox Marxist in the Leninist mold, and his purpose was to apply Marxian methods and categories to the Soviet economy as it existed in the period of the New Economic Policy. What was "new" was the character of this economy: all the theoretical tools and concepts were taken, with but few

modifications, from Marx. This will doubtless make the book difficult going for non-Marxists; some may even find it quite incomprehensible. It is perhaps worth noting, therefore, that as a Marxist I found Preobrazhensky's exposition a model of clarity and lucidity, a far cry from the kind of "Marxian" scholasticism which has become so common in recent decades. The high intellectual level, the evident scientific spirit, and the absence of jargon and dogma in Preobrazhensky's work make one realize how seriously Marxism was set back in the USSR—and not only in the USSR—as the result of the ideological needs of the Soviet leadership in the period of forced industrialization, war, and cold war.

Where bourgeois economics has always sought to find and emphasize the elements of harmony, equilibrium, and cooperation in a socioeconomic system, Marxism has done just the opposite in the conviction that both structure and change are dominated by contradiction, opposition, and struggle. In keeping with this approach, Preobrazhensky saw the Soviet Union in the 1920's as a strictly transitional society composed of two totally opposed systems locked in mortal combat. One of these systems was simple commodity production (peasant agriculture, handicraft production, petty trade), the other was that of emerging socialism (industry, transportation, communications, finance, all owned by the state). The private economy was governed by the "law of value," which in Marxian usage is roughly equivalent to Adam Smith's "invisible hand"—in other words, it responded to and was shaped by competitive market forces. If the socialist sector should content itself with the role of catering to the needs of the still much larger private economy, it would become a mere appendage of the latter and sooner or later would be disintegrated and taken over: this, in short, would be the road to the restoration of capitalism. The alternative was for the state deliberately to build up the socialist sector, not in response to the pattern of effective demand generated by market forces, but with a view to the transformation of the country's economic structure and the eventual absorption of the private economy. This was the road to a fully socialist society.

Preobrazhensky was of course a passionate partisan of the socialist alternative, and he took it for granted that the Soviet state was committed by its class character to follow this road. His central purpose in *The New Economics* was to spell out what this implied and to identify and analyze the difficulties and obstacles which would have to be overcome.

This background should help to clarify what Preobrazhensky meant by the "law of primitive socialist accumulation," which he insisted was the governing law of the socialist sector of the Soviet economy and which he counterposed to the law of value as the governing law of the private sector. "Primitive accumulation," it will be recalled, was the term Marx applied to the appropriation, usually by violent methods, by the nascent capitalist class of wealth (land, precious metals, currently produced surpluses) of precapitalist countries and population strata.¹ This process, Marx held, was essential to the es-

¹ Marx actually used the word *ursprünglich*, which would have been better translated by its literal equivalent "original"; what he wanted to stress was that this kind of forcible accumulation *preceded*, and laid the foundations for, capitalist accumulation proper.

establishment of capitalism, and later on the continued plundering of precapitalist peoples added to and accelerated the process of capitalist accumulation. "Primitive socialist accumulation," as seen by Preobrazhensky, was an analogous process whereby the nascent socialist state appropriates the surplus product of the private sector and channels it into the socialist sector to speed up the growth of the latter. Preobrazhensky believed that the socialist state was precluded by moral and political considerations from having recourse to the violent methods used by capitalism; its primary methods would have to be taxation and a monopoly price policy by state-owned industries. Little did he guess what violent forms the process would take under Stalin's forced-collectivization program only a few years later!

By speaking of a "law" of primitive socialist accumulation, Preobrazhensky meant no more—and no less—than that the policy of taking from the private sector to accelerate the growth of the public sector was one which, in the conditions which existed in the USSR in the 1920's, the socialist state must necessarily adopt in order to survive as a socialist state. This is not the same meaning as the term has in the "law of value" where it signifies certain regularities which impose themselves regardless of the will, or even knowledge, of the people involved. The reader who keeps in mind that Preobrazhensky used the word "law" in these two quite different senses will find it easier to follow his arguments.

The focus of all these arguments was the policy of the Soviet state at the time the book was being written, and many of them are couched in a highly polemical form. For these reasons it seems clear that a reasonable knowledge of the historical context is essential to get the most out of Preobrazhensky's work.² This fact, however, should not be allowed to give rise to the assumption that *The New Economics* has only an historical interest. Many of the problems which were faced by the USSR in the 1920's exist today in countries which are struggling to break out of the prison of underdevelopment, and anyone who is interested in them, and in particular in working out viable solutions for them, is sure to find this a stimulating and valuable work. I subscribe wholeheartedly to the judgment of Ernest Mandel, the Belgian Marxist who wrote the Introduction to the French translation of the book (*La Nouvelle Economique*, Paris, 1966): "... one will not find in this book a code of conduct for economic leaders of underdeveloped countries engaged in the transition from capitalism to socialism. But one does find in it an arsenal of concepts and chains of analysis which permit the freeing of the elaboration of political economy in these countries from the grip of empiricism and vulgar pragmatism. One finds the essential instruments for defining, in all such cases, the great options and the lines of possible evolution. *The New Economics* is not only a guide to the better understanding of these basic problems and thus to an escape from debilitating pragmatism. It is also a weapon for cutting these Gordian knots, not in the sense of some academic truth but in the inter-

² Apart from general works on Soviet history, the most useful companion volume to *The New Economics* is Alexander Erlich, *The Soviet Industrialization Debate 1924-1928*, Cambridge, Mass., 1960.

ests of a class and of a cause to which Preobrazhensky devoted his whole life: the working class and the cause of socialism."

PAUL M. SWEETZ

New York, N.Y.

Private and Public Planning. By NEIL W. CHAMBERLAIN. New York: McGraw-Hill Book Co. 1965. Pp. viii, 238. \$7.95.

Professor Chamberlain's study is about private and public planning in the proportion of one rabbit to one horse—40 pages on private planning and 174 on public, with 16 on definitions used in both. The discussion of private planning is intended to introduce and illustrate certain ideas which will then be applied to the analysis of public planning. These ideas constitute, according to the author, "whatever contribution this study makes." They include "the conception of planning as the systematic management of assets, the inescapable conflict of objectives between system and subsystem, and the consequent dependence not only on technical-economic but also organizational-political coordination; the ongoing nature of the planning process, with a continuing interplay between intent and event, and the significance of the distinction between what are here called specific and categorical social objectives."

We may have encountered these ideas before in plainer garb. I must confess a certain irritation at the repeated use of "subsystems" or, worse, "subunits" for what turns out to be "people." Nevertheless, these would probably be a useful set of ideas for analyzing public planning. The distinction between the technical-economic and organizational-political aspects seems to me especially promising. However, an analysis of public planning in these terms does not come through. Rather we get an anecdotal account of government planning in Western Europe in the postwar period on which these ideas have been plastered without apparent necessity or effect. The reason is, I think, that we just do not know enough about what is really going on in the public planning process, about the objectives of those who do it, about the techniques employed, and about the results achieved or thought to have been achieved, to subject the process to any sophisticated analysis. It is as if we are listening to a professor of art analyze a painting in a room so badly lit that we can't see the object. Symptomatic of how little we know about the object being analyzed is the fact that in the leading case, French "indicative" planning, even the practitioners don't know, or disagree about, what the method is.

Chamberlain starts with a definition of planning as the systematic management of assets, something that even U.S. businesses do and that therefore is not the property of the Socialists or the Communists. The operation of the U.S. Department of Defense under Secretary McNamara is cited as "perhaps the purest, although partial, example of governmental planning in the West today." But that is the last we hear of the Department of Defense. Chamberlain is not interested in partial planning, however pure. He is interested in comprehensive and detailed management of the economy, however, impure. Whether the kinds of government policies to which this book is mainly devoted meet the author's definition of planning as "systematic" is never asked,

although it is pretty obvious that most of them do not. The test applied is not that the government's management of the "nation's" (whose?) assets should be systematic, but that there should be a lot of it.

The author probably did not intend to give comfort to those who believe that any government "intervention" in the economy is the narrow edge of the wedge leading inevitably to total dictatorship. But this is precisely the impression given. From modest origins, the objectives and necessary techniques of government economic management grow in this short and undramatic book by inexorable logic until the requirements of "planning" threaten to devour all other social institutions. In the end, even the poor old Congress is on the verge of mummification because it does not fit in with a long-run, expert, and functionally representative management of our economy.

As one example of this inevitability, the really very interesting discussion of incomes policy may be cited. "However reluctantly governments have been driven to the conclusion, a price and incomes policy is an essential ingredient in management of the economy." There follow a number of convincing pages showing that none of the policies heretofore tried has worked or could work. Then we are treated to several new, "unorthodox" suggestions, each more quixotic than the last. But still, there is no government management without incomes policy, and if you can't make an incomes policy work, have one anyway.

The basic problem with this book is not that it is a very ideological book or that its ideological argument is thin, both of which are true. The basic problem is that the book doesn't tell the reader very much about postwar economic policies and actions (to avoid the charged word "planning") in Western Europe. There is no consecutive account of what happens in any country on any subject. Somewhere between systems theory and ideology, the facts got lost. But there is much internal evidence that Chamberlain has had exceptional opportunities to learn, and knows a great deal about what has been going on in Western Europe. If he would now write this down, he would make a real contribution.

Business Fluctuations

American Economic Association Readings in Business Cycles. Edited by ROBERT AARON GORDON and LAWRENCE R. KLEIN. Homewood, Ill. Richard D. Irwin, Inc., 1965. Pp. x, 731. \$8.50.

Random shocks, acceleration principle, ratchets, permanent income, and econometrics! Take your pick, or put them all together, and you have the business cycle. Or do you?

The current sequel to the AEA's *Readings in Business Cycle Theory*, which played a major part in the graduate education of the post-World-War-II generation of economists, has a couple of welcome prewar articles but otherwise is devoted to papers reflecting work of the last two decades. It gives good rep-

resentation to the resurgence of flexible accelerator models in an initial section on "Theory," which includes an article by Goodwin, Hicks's review of Harrod's *Towards a Dynamic Economics*, presenting the guts of his own *Trade Cycle*, the Smithies (1957) *Econometrica* article adding ratchet effects and a profit-dominated investment function, Minsky's "A Linear Model of Cyclical Growth," and a delightfully clear, classic paper on inventory cycles by Metzler (*Review of Economic Statistics*, 1941). The section on theory is concluded with a Haberler effort to redress the balance, as he sees it, by emphasizing the role of monetary factors.

The next group of reprints, on "Methodology," contains Frisch's (1933) "Propagation Problems and Impulse Problems in Dynamic Economics," which it is particularly good to have accessible. The section also includes the Koopmans-Vining exchange, which holds up rather well and may be read with interest or profit by the old and the young and will probably have little influence on most practitioners.

Section III on "Econometric Models" comprises the Duesenberry-Eckstein-Fromm "A Simulation of the United States Economy in Recession," the examination of "The Dynamic Properties of the Klein-Goldberger Model" by the Adelmans, and Christ's review of models of Tinbergen, Klein, Klein and Goldberger, and himself.

Section IV on "Studies of Particular Variables" offers Kisselgoff and Modigliani and Jorgenson on investment, Ando and Modigliani and Farrell on new theories of consumption, and Friedman's 1958 *Journal of Political Economy* application of the permanent income concept to the demand for money. It also includes Lipsey's discussion of Phillips curves of unemployment and wage-rate changes (1960) and a 1962 report by Geoffrey Moore on work of the National Bureau of Economic Research.

Section V on "Long Cycles" includes articles by Abramovitz and O'Leary and by W. Arthur Lewis. Section VI on "International Aspects" contains a bold, interesting econometric effort by Polak and Rhomberg at analyzing the transmission of disturbance between broad groups of nations. In Section VII on "Forecasting," Suits points with understandable pride (1962) at results of his continuing use of an econometric model, and Alexander and Theil and Jochems report on diffusion indexes in the analysis of economic and business data.

The final section on "Policy" includes one of Phillips' interesting and sobering papers exploring the dynamic implications of some stabilization mechanisms. It also contains an excellent presentation of the balanced budget theorem by William Salant and articles by Heller and Schlesinger, differing predictably in their evaluations of automatic and discretionary monetary and fiscal policies.

There is much that one can say, article by article, about a volume of papers such as these, frequently by distinguished authors, and clearly designed to sample major aspects of recent work on business cycles. I will permit myself a number of scattered observations, both critical and approving, and then some general reflections.

While the editors explicitly eschew attention to growth models, much of the

theoretical section has an underlying motif of Hicksian fluctuations around a long-run growth path bounded by ceilings and floors. It might be well, therefore, to rehabilitate the oft-criticized "autonomous investment" which is Hicks's exogenous moving force. This may be done by a simple assumption and semantic twist. For "autonomous investment" read "autonomous expenditure" and assume that *this* grows at a more or less constant rate dictated by growth in population and growth in the minimum standard of living which people will insist upon maintaining by means of dissaving, borrowing, private charity or government expenditure or relief. All of this may be imbedded in the ratchet effects of Duesenberry, Eckstein and Fromm, Smithies, and Minsky, but someone ought to set it forth in terms of either individual maximizing behavior or the necessary assumption for viability of the socioeconomic system whose behavior we are trying to explain.

Having referred to growth models, I cannot let pass the opportunity to correct again a widespread misinterpretation of Harrod's warranted rate of growth. For Smithies, unfortunately in good and numerous company, repeats the mistaken argument that the warranted rate of growth is a full-employment rate. But Harrod was quite explicit in asserting that his " G_w is the entrepreneurial equilibrium; . . . in Keynesian fashion he contemplates the possibility of growing 'involuntary' unemployment" (*Towards a Dynamic Economics*, p. 87). And this, I would insist, is quite basic to the analysis.

It is interesting to reread Frisch's article setting forth the role of erratic shocks in the light of the Adelmans' analysis of the Klein-Goldberger models and a pregnant observation by Haberler on the "contributions" of the major periodic shocks of wars. But in view of the large role in business cycles attributed by many to fluctuations in investment, these might have somewhere received further, systematic attention. (Or is this reviewer being too parochial?) For one thing, I continue to view with some dismay the argument that "the dominant influence on the rate of gross investment decisions is the level of present or past gross profits" (Smithies, p. 43). This is not readily squared with appropriate theory that investment relates to the expected contribution of investment to profits and not expected profits per se, let alone past or current profits. The Kisselgoff-Modigliani article puts the matter in better theoretical and empirical perspective but is cautious in generalizing the particular characteristics of the electric power industry to which it relates. Jorgenson does set forth a general theoretical model but may unfortunately mislead the reader, in his cryptic presentation, as to the extent to which his results reflect empirical findings as opposed to the specific assumptions of his model. In particular, Jorgenson presents empirical estimates of distributed-lag relations between his measures of actual and desired capital stock. But his "responses and elasticities of investment with respect to changes in market conditions and tax structure" (p. 377) reflect essentially his own assumed relation between equilibrium capital stock and prices of output and capital, rate of interest, and tax and depreciation rates. No empirical evidence of separately identifiable roles of these factors is presented.

It is particularly welcome to have income expectations and assets brought explicitly into treatment of the consumption function, as in the Ando and Mo-

digliani and Fisher articles. This is surely more sound than earlier empirically oriented reliance on previous income peaks and ratchet effects. Farrell's references to acceleration-type investment in consumer durables and capital gains are also welcome. Sound economic treatment of the role of capital gains in income and consumption is indeed long overdue.

Lipsey's interesting review of the relation between wages and unemployment, perhaps inadvertently highlighting major gaps in our understanding, offers a theoretical rationale which dwells on supply and demand relations really meaningful only for individual industries. Empirical estimates of a dynamic theory appropriate at the aggregative level are not to be found. Nor indeed do we see attention to the possibly varying effects over the cycle of imperfectly competitive forces in both product and labor markets.

It was good to see Alexander's warning on the false as well as correct leads noted in diffusion indexes. And Theil and Jochems offer some jolting information on the uncertainty or inaccuracy of business responses on *ex post*—let alone *ex ante*—data. This may suggest to some the disutility of sophisticated theoretical and statistical treatment of business data. I see rather a cue for more stubborn persistence in applying data to theoretical relations that make sense rather than merely following "the facts" in broadly impressionistic interpretations. (I fear that I am relatively unmoved by many of the charts and tables of conformities reported by the National Bureau of Economic Research and its associated scholars. I prefer explicitly stated mathematical relations and estimates of coefficients and standard errors.)

But this may well lead to a general observation. While one can hardly expect a collection of 31 separate pieces by about as many different authors to present a unified analysis of the business cycle, and while one should congratulate the editors for choosing a broad sample of the various areas of activity, one may be impressed by the numbers of prominent economists working without contact with any central theme. Much of the theoretical work involves the construction and manipulation of fairly mechanical relations with no clear grounding in maximizing or sensible behavior. The econometric studies are frequently forced in the direction of such mechanical relations by lack of appropriate data. But we really do not want another generation arguing about whether consumption is a linear function of this period's income or last or whether investment must "lead" the peak in consumption.

For people should not be expected to react to the past. Decisions must relate to initial conditions and expectations of the future. And here is where the most intractable difficulties develop. It is very difficult to find a stable relation between expectations of the future and observable past variables or initial conditions. Changes in taxes, government expenditures, monetary policy, consumer demand, and income may all have quite different effects as they relate differently to expectations of the future. Analysis and prediction of business cycles will remain sharply limited in their power as long as this nexus from past to present to future is so incompletely specified.

It is a merit of this volume and of the work which it samples that some of these considerations, along with the use of more systematic econometric techniques for the application of data to theory, have come to the fore. The cur-

rent generation of graduate students and their instructors should find it a useful introduction to recent research and analysis of business cycles.

ROBERT EISNER

Northwestern University

Money, Credit, and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

Determinants and Effects of Changes in the Stock of Money, 1875-1960. By PHILLIP CAGAN. National Bureau of Economic Research Studies in Business Cycles No. 13. New York and London: Columbia University Press, 1965. Pp. xxviii, 380. \$10.00.

A persistent association of money stock, prices, and output has been demonstrated for many different periods and institutional environments. The observations have been interpreted in three different ways. One attributes the pattern to a causation running from money to prices and output. Another notion reverses the line of causation, and a third admits a mutual interaction of real and monetary processes. The evaluation of the rival interpretations usually relied on a more or less detailed analysis of the chain linking money with output. Economists have only recently become aware that a study of money-supply patterns provides useful information bearing on the comparative relevance of the alternative interpretations.

The book authored by Phillip Cagan and recently published by the National Bureau of Economic Research thoroughly exploits these opportunities. It begins with an excellent description of the major issues. This material is systematically organized with the aid of an analytic framework which reduces variations in the money stock (measured in the inclusive sense following the Friedman-Schwartz procedures) to changes in high-powered money H (i.e., the monetary base), the banks reserve ratio r , and the currency ratio c . The formula $M = H[c(1-r) + r]^{-1}$ also guides the author's search for useful hypotheses. The formula has, by itself alone, no empirical content. This poses no problem so long as the author expands beyond the initial statement in a search for fruitful explanations of the entities H , r , and c proximately "determining" the money stock. His search begins with a careful description of the secular and cyclic movements of the money stock and the relative contributions made by the three proximate determinants. The results deserve a close scrutiny by monetary theorists and in particular the most diligent attention of future textbook writers.

This detailed examination of secular and cyclic patterns of the money stock yields useful clues bearing on the nature of the money-supply mechanism. These clues are systematically explored in subsequent chapters. The inquiry opens with a thorough and penetrating analysis of secular and cyclic movements of the monetary base. These studies successfully mesh description and analysis. The shifting arrangements governing the supply of base money are patiently investigated and their manner of operation carefully traced. Changes in the gold stock, silver purchases, Treasury operations, and the issue of na-

tional bank notes determined before 1914 the changes in the base. After 1914 the portfolio of Federal Reserve Banks loomed as an important determinant. The background of these source-components is illuminated, their behavior characterized and explained, and their relative importance indicated.

The cyclic patterns underlying the movement of the base are singularly instructive. Both Chart 7 on page 102 and Chart 24 on page 271 show a remarkable change in the cyclic behavior of the base around World War I. Before this period the growth of the base reached a peak in stage VII, about midway during the economic downswing. It rose sharply before and fell even more decisively in subsequent stages. After the war a peak was reached in stage III or IV; in the later phases of economic expansion and before the peak of activity. There followed a retardation through most of the economic decline until after stage VIII, or almost the end of the downswing. The charts also demonstrate that this substantial change in cyclic patterns cannot be attributed to the gold movements, but resulted from the behavior of the nongold sources of the base, which was essentially from the emergence of Federal Reserve credit. An adequate explanation of these observations thus leads us to the peculiar policy conception centered originally on bank borrowing and later on free reserves which has dominated the policy-makers' view since the 1920's. It can be shown that policies emanating from a "free reserve conception" generate the behavior of Federal Reserve credit so intriguingly described by the author's charts.

The role of the currency ratio has rarely been properly recognized in the literature. Here the author pioneers with his investigations of the secular and cyclic movements of this ratio. His efforts certainly contribute to the emergence of a reasonably satisfactory explanation of the longer-run behavior of the currency ratio. On the other hand, the cyclic evolutions of the ratio remain substantially unexplained. It is not clear whether the pattern conforms positively or inversely to the cycle. The author's choice of an inverse pattern is not convincing at this stage. The unsatisfactory state of affairs is also clearly revealed in the attempted explanations. The suggestions offered by Mitchell and Hawtrey yield very little, but neither can I find the author's suggestion of linking currency demand with a permanent expenditure concept very helpful. It may be useful to reconsider the author's framework guiding his search for explanations. The ratio is exhibited as a product of three factors: the ratio of currency to consumers' expenditures, income velocity, and the ratio of consumers' expenditures to income. The author attempts to explain the currency ratio in terms of the three new ratios. The underlying idea appears very sound indeed. The factoring decomposes the ratio into separate entities which permit a useful classification of a host of relevant substitution processes reflected by the currency ratio. But I would argue that the first and second factors substantially overlap and effectively prevent a useful separation. For precisely this reason Meltzer and I worked with the ratio of currency to check deposits (in lieu of Cagan's ratio to the inclusive money stock). The more narrowly conceived currency ratio can be equated with the product of two ratios, viz., the ratio of transactions-velocity of deposits to the transactions-velocity of currency and the value of currency transactions per dollar of deposit transactions. The difficulties encountered on the author's path suggest that the alter-

native approach may be usefully explored.

The literature has frequently emphasized the potentially volatile redistribution of deposits and the consequent serious obstruction to monetary policy. The chapter on the reserve ratio effectively eliminates such useless speculations. A solidly detailed investigation of all kinds of deposit redistributions (between national and nonnational banks, between member banks and nonmember banks, between classification of member banks, between time and demand accounts) establishes that these changes exert in general a minor influence on the banks' average reserve ratio. They explain consequently only a vanishing portion of the (inclusive) money stock's behavior. This result carries over to the exclusive money stock with the exception of the distribution between time and demand deposits. It should also be noted that the author's results bearing on the latter distribution are conditional on his choice of a currency ratio. Under the alternative approach noted before, the redistribution between demand and time deposits operates also through a channel independent of the reserve ratio on the money stock. The alternative approach assigns therefore a substantially larger effect to redistributions between time and demand accounts.

Reserve requirements shaped the banks' average reserve ratio much more importantly than deposit redistribution. It has been argued on occasion that changes in requirements only modify the "usable ratio," i.e., the ratio of reserve money in excess of requirements to total deposits, with no effect on the total ratio. Cagan investigates this issue carefully and finds that the usable ratio does not depend significantly on the legal ratios. In particular, he finds that after 1948 the usable ratio returned speedily to the previous level whenever requirements were changed. Before 1948 the usable ratio apparently absorbed a good portion of the legal changes. However, the author's interpretation of the observed movement is not sufficiently supported. Compensatory open-market policies accompanied every change in requirement ratios from 1948 to 1960. Compensation was usually very pronounced and quite immediate. This implies that changes in required reserves were matched by closely corresponding changes in total reserves. The immediate return to usable ratios thus reflects to a large extent such compensatory policies and yields little evidence with respect to the banks' adjustment to changes in legal ratios.

The usable reserve ratio forms the last explanatory component of the reserve ratio explored by Cagan. He wrestles first with explanations of its remarkable decline over the period studied. Market rates of interest move in the wrong direction and thus cannot explain the movement. A variety of institutional changes are mentioned by the author whose joint effect lowered the marginal benefit of usable reserves. His argument appears convincing. Nevertheless, one wonders whether the same or related changes did not simultaneously lower relevant marginal costs. Marginal costs of negotiating and transacting, or marginal costs of information bearing on loan customers, or marginal costs of portfolio readjustments may have fallen substantially since the early 1870's. Their reduction would also have lowered the usable ratio. Further research appears appropriate on this point.

The analysis of cyclic patterns carefully separates the effect of panics and severe depression. The effect of the latter is most likely negligible, whereas the

tional bank notes determined before 1914 the changes in the base. After 1914 the portfolio of Federal Reserve Banks loomed as an important determinant. The background of these source-components is illuminated, their behavior characterized and explained, and their relative importance indicated.

The cyclic patterns underlying the movement of the base are singularly instructive. Both Chart 7 on page 102 and Chart 24 on page 271 show a remarkable change in the cyclic behavior of the base around World War I. Before this period the growth of the base reached a peak in stage VII, about midway during the economic downswing. It rose sharply before and fell even more decisively in subsequent stages. After the war a peak was reached in stage III or IV; in the later phases of economic expansion and before the peak of activity. There followed a retardation through most of the economic decline until after stage VIII, or almost the end of the downswing. The charts also demonstrate that this substantial change in cyclic patterns cannot be attributed to the gold movements, but resulted from the behavior of the nongold sources of the base, which was essentially from the emergence of Federal Reserve credit. An adequate explanation of these observations thus leads us to the peculiar policy conception centered originally on bank borrowing and later on free reserves which has dominated the policy-makers' view since the 1920's. It can be shown that policies emanating from a "free reserve conception" generate the behavior of Federal Reserve credit so intriguingly described by the author's charts.

The role of the currency ratio has rarely been properly recognized in the literature. Here the author pioneers with his investigations of the secular and cyclic movements of this ratio. His efforts certainly contribute to the emergence of a reasonably satisfactory explanation of the longer-run behavior of the currency ratio. On the other hand, the cyclic evolutions of the ratio remain substantially unexplained. It is not clear whether the pattern conforms positively or inversely to the cycle. The author's choice of an inverse pattern is not convincing at this stage. The unsatisfactory state of affairs is also clearly revealed in the attempted explanations. The suggestions offered by Mitchell and Hawtrey yield very little, but neither can I find the author's suggestion of linking currency demand with a permanent expenditure concept very helpful. It may be useful to reconsider the author's framework guiding his search for explanations. The ratio is exhibited as a product of three factors: the ratio of currency to consumers' expenditures, income velocity, and the ratio of consumers' expenditures to income. The author attempts to explain the currency ratio in terms of the three new ratios. The underlying idea appears very sound indeed. The factoring decomposes the ratio into separate entities which permit a useful classification of a host of relevant substitution processes reflected by the currency ratio. But I would argue that the first and second factors substantially overlap and effectively prevent a useful separation. For precisely this reason Meltzer and I worked with the ratio of currency to check deposits (in lieu of Cagan's ratio to the inclusive money stock). The more narrowly conceived currency ratio can be equated with the product of two ratios, viz., the ratio of transactions-velocity of deposits to the transactions-velocity of currency and the value of currency transactions per dollar of deposit transactions. The difficulties encountered on the author's path suggest that the alter-

native approach may be usefully explored.

The literature has frequently emphasized the potentially volatile redistribution of deposits and the consequent serious obstruction to monetary policy. The chapter on the reserve ratio effectively eliminates such useless speculations. A solidly detailed investigation of all kinds of deposit redistributions (between national and nonnational banks, between member banks and nonmember banks, between classification of member banks, between time and demand accounts) establishes that these changes exert in general a minor influence on the banks' average reserve ratio. They explain consequently only a vanishing portion of the (inclusive) money stock's behavior. This result carries over to the exclusive money stock with the exception of the distribution between time and demand deposits. It should also be noted that the author's results bearing on the latter distribution are conditional on his choice of a currency ratio. Under the alternative approach noted before, the redistribution between demand and time deposits operates also through a channel independent of the reserve ratio on the money stock. The alternative approach assigns therefore a substantially larger effect to redistributions between time and demand accounts.

Reserve requirements shaped the banks' average reserve ratio much more importantly than deposit redistribution. It has been argued on occasion that changes in requirements only modify the "usable ratio," i.e., the ratio of reserve money in excess of requirements to total deposits, with no effect on the total ratio. Cagan investigates this issue carefully and finds that the usable ratio does not depend significantly on the legal ratios. In particular, he finds that after 1948 the usable ratio returned speedily to the previous level whenever requirements were changed. Before 1948 the usable ratio apparently absorbed a good portion of the legal changes. However, the author's interpretation of the observed movement is not sufficiently supported. Compensatory open-market policies accompanied every change in requirement ratios from 1948 to 1960. Compensation was usually very pronounced and quite immediate. This implies that changes in required reserves were matched by closely corresponding changes in total reserves. The immediate return to usable ratios thus reflects to a large extent such compensatory policies and yields little evidence with respect to the banks' adjustment to changes in legal ratios.

The usable reserve ratio forms the last explanatory component of the reserve ratio explored by Cagan. He wrestles first with explanations of its remarkable decline over the period studied. Market rates of interest move in the wrong direction and thus cannot explain the movement. A variety of institutional changes are mentioned by the author whose joint effect lowered the marginal benefit of usable reserves. His argument appears convincing. Nevertheless, one wonders whether the same or related changes did not simultaneously lower relevant marginal costs. Marginal costs of negotiating and transacting, or marginal costs of information bearing on loan customers, or marginal costs of portfolio readjustments may have fallen substantially since the early 1870's. Their reduction would also have lowered the usable ratio. Further research appears appropriate on this point.

The analysis of cyclic patterns carefully separates the effect of panics and severe depression. The effect of the latter is most likely negligible, whereas the

former induces a prolonged and slowly decaying response. The author acknowledges that interest rates do play a role. A concern with gross association permits, however, the discovery of their effects only for periods dominated by extreme variations in market rates. It is no surprise therefore than an effect of interest rates can only be discerned for the 1930's. The author concludes ultimately that interest rates cannot explain the cyclic changes in the usable ratio and associates these changes through loan demand with business conditions. His argument remains too vague to be convincing. The cyclic role of interest rates is probably submerged by their joint interaction with marginal costs of loan-extension and portfolio readjustment.

The detailed investigations of money-supply mechanisms are ultimately exploited for an evaluation of the lines of causation linking money, prices, and economic activity. If causation runs essentially from the economy to money, then it must be shown how the base, the currency, and reserve ratio are determined by economic evolution. The author thoroughly and convincingly argues that the secular patterns investigated are inconsistent with a causation from economic activity to money. The cyclic movements on the other hand are more ambiguous. They reveal a substantially greater dependence for money supply on economic activity and the causation from money to output and prices is difficult to separate. The author selects therefore a number of special events for a detailed study. Wartime inflations and severe depressions yield substantial evidence for the relevant causal operation of money. The author still concludes that most of the cyclic variations in the money stock are due to changing business conditions. This statement is quite consistent with a pronounced line of causation from money to business, but recent observations raise serious doubts concerning the author's contentions. We computed for each postwar cycle the ratio of (both exclusive and inclusive) money stock at the end of each half-cycle to the money stock at the beginning of the half-cycle. Similar ratios were computed for base and monetary multiplier. Rank correlations between money ratios, base, and multiplier ratios emphasize the dominant position of the base over half-cycles. The cyclic dependence of money on business would thus be mediated through the policy-makers' conception underlying the cyclic behavior of the base. One wonders how much dependence would remain should the conception miraculously change to generating a regular growth in the base. It is not unlikely that under these circumstances the cyclical dependence of the money stock on business would be seriously attenuated.

The book contains many excellent passages worthy of attention. There also remain serious unresolved issues, and the careful reader will be left on occasion with substantial doubts and open questions. It is however difficult to criticize the author severely for these inadequacies when we consider that systematic investigations of money-supply mechanisms re-emerged only recently. Since Cagan's first contribution to monetary theory, one has become accustomed to expect his efforts to yield a useful product of quality. Our expectation has not been in vain.

Ohio State University

Money, Interest, and Prices—An Integration of Monetary and Value Theory.
2nd ed. By DON PATINKIN. New York: Harper & Row, 1965. Pp.
xxv, 708.

The reviewer of the second edition of an already-celebrated book has both a duty and an opportunity: a duty to report on the new material and an opportunity to present a revaluation of the book as a whole. No author could have been more helpful to a reviewer in the first task. Not only are the main changes announced in the Preface, but a detailed account of them is also given in a supplementary note. Two of the more important changes can be accepted as unqualified improvements. These are, first, the incorporation of the Gurley-Shaw distinction between "inside" and "outside" money into the analysis of issues concerned with the neutrality of money and other related matters in Chapter 12; secondly, the incorporation, in the particular context of the simplified money-and-goods model of Chapter 3, of the Archibald-Lipsey analysis of long-run equilibrium.

I have some reservations, however, concerning the most substantial revision of all. This is the elaboration in Chapters 5-7, based on the work of Baumol, Markowitz, and Tobin, of the microeconomic theory of money. Two alternative explanations of the demand for money are presented. In the first place, money is regarded as a consumer good, the holding of which gives subjective utility to the individual. In the second place, money is regarded as a producer's good, and money is held only as a means of achieving a more desirable basket of commodities over time. While there is much that is of value and of interest in these chapters, some of the analysis seems to raise more questions than it answers. For example, in the utility approach the holding of money is regarded as having utility for the individual by giving him a sense of security, of freedom from likely trouble and embarrassment. But should one stop there? The author himself goes a bit further in the Mathematical Appendix, where he treats of a model in which bonds as well as money have liquidity. But even this may not be going far enough. Any departure from the assumption that the consumption of commodities is the sole end of economic activity opens the door to all sorts of speculations. May not the individual obtain satisfaction from the mere holding of wealth as such, or from its acquisition? Why should the *liquidity* of assets be singled out as the one feature of wealth-holding that gives subjective satisfaction? Though very little that is definite or of operational significance can be said about these matters, they may nevertheless be of some analytical importance. For if it is true that individuals obtain subjective satisfaction from the holding and the acquisition of wealth, then this could lend some support for the Keynesian emphasis on the substitution between money and other assets, as against the substitution between money and commodities.

However, my main worry about these chapters is that they impair the unity and sweep of the book. For one thing, they are of a different order of difficulty from the rest of the text. The reader who comes to them feels like the novice mountaineer who has been congratulating himself on his progress up the mountain, only to find himself faced with a pitch of real severity. And it is not at all certain, nor would the author claim, that this is the only possible route to the summit. The student who on a first reading finds difficulty with the in-

tricate analysis of these chapters would be well-advised to pass on at once to Chapter 8 and come back to them later.

The book as a whole gains stature on renewed acquaintance. The main themes, that the real-balance effect is essential for the integration of monetary and value theory, that the dichotomization of the economic system into a market for goods in which relative prices are determined and a market for money in which absolute prices are determined is invalid, that Say's identity is appropriate for a barter economy but not for a monetary economy—all these by now familiar propositions and others have, in the reviewer's opinion, stood up well to the test of time and of the many assaults that have been made on them. But perhaps the strongest impression left by the book is of the author's integrity as a controversialist. Although a considerable part of the book is devoted to a critical analysis of the writings of others, a "mere debating point" is nowhere to be found in these pages. When referring in the Preface to the criticisms of the earlier edition that he has not been able to accept, Professor Patinkin writes: "My primary objective in such cases has been the necessary clarification of substantive issues, and not polemics. I cannot, however, pretend that I have not on occasion strayed across the indefinite line that separates these two." Let him, above all, be reassured on this score.

CHARLES KENNEDY

University of the West Indies

Traité d'économie bancaire. Vol. I, *Les institutions de banque.* By JACQUES BRANGER. Paris: Presses Universitaires de France, 1965. Pp. xii, 400. F 48.

Despite its ambitious title this is an elementary—if comprehensive—text-book on French financial institutions, written by a practitioner. The author, the president of a semipublic financial establishment, is publishing the text of a course he teaches at a school of engineering. A second volume will cover credit operations.

An improbable first chapter on the genesis of the credit economy and "the banker through the ages," featuring a parody of Kipling's poem, *If* ("... you'll be a Banker, my son!"), and a few oversimplified pages on the role of credit in the economy introduce the first part of the book, a "General History of Banking and Credit" from prehistory to the creation of the Bank of France. These 48 pages could advantageously have been dispensed with, inasmuch as the succeeding sections on the various credit establishments include lengthy paragraphs on their particular histories. Jacques Branger is obviously not a specialist and can only present a series of second-hand vignettes on Babylon, the Medicis, or the Bank of Amsterdam.

The second part, about two-thirds of the book, is a description of the major financial institutions in France. It also includes a chapter on the regulation of banks and financial intermediaries and another on the French franc area. After these two chapters and one on the Bank of France, Branger covers successively commercial banks and the private financial organizations, the semi-public intermediaries, and the public financial services. This second part is a handy catalogue, generally exhaustive (there is even a paragraph on C.O.D.

mail, although no mention is made of the GICEX consortium in export credit institutions), and the author can hardly be blamed for devoting more space to his own outfit than to any other, except the Bank of France. The exposition suffers from its separate treatment of institutions (this volume) and operations (volume two). The reader is not spared any detail on the board composition of the regional branches of the Bank of France, yet he has to wait for the second volume to be published to learn about the limits to rediscounting operations and the monetization of medium-term credit. The arrangement of the chapters could also have been improved upon; the chapter on the franc area, for instance, follows immediately that on the Bank of France while the role of the Treasury is discussed some 300 pages later.

The last part of the book devotes only six pages to a quantitative survey of the financial sector and a simplified flow of funds statement for the economy. It is unfortunate that this section is so limited. For one thing, the book badly needs figures on the relative importance of the various sectors and establishments, as this type of information cannot easily be ascertained from the text. It takes some hard research, for example, to find out that postal checking accounts represent more than 20 per cent of total demand deposits, and postal savings accounts almost 30 per cent of all time deposits. This section could have emphasized the major characteristics of French financial institutions, the importance of the public sector, the strong liquidity preference of the general public, the underdevelopment of the financial market, and the resulting use of short-term resources collected by the financial intermediaries for medium- and long-term uses. Branger could also have made use of the sources of information available through France's pioneering efforts in the integration of flow of funds statements with national accounts.

After a lame chapter on international development finance and another on the creation of new types of financial institutions in France (such as regional development corporations and mutual funds), the book ends with an odd assortment of quotations from various personalities, including the present heir to the French throne, on the future of banking, the inflationary consequences of French planning, and the need to stimulate saving.

In spite of its shortcomings and Branger's annoying remarks (sample: he suggests that the *Crédit Municipal*, because of its similar problems, is particularly competent to appraise the financial difficulties of its customers [p. 273]; or, "Should we recall that the postal checking accounts have been nicknamed 'Treasure of the Treasury'?" [p. 310]), the book will perform a valuable reference service for the reader interested in the institutional organization of French credit establishments. It is also to be hoped that textbook writers in this country will find there profitable suggestions for the organization of their subject matter. Isn't it time that students of money and banking acquaint themselves with other financial institutions than commercial banks and be offered a complete picture of the financing of an economy?

PATRICK B. DE FONTENAY

International Bank for Reconstruction and Development

Public Finance; Fiscal Policy

Essays in Fiscal Federalism. Edited by RICHARD A. MUSGRAVE. Washington, D.C.: The Brookings Institution, 1965. Pp. xvi, 301. \$6.00.

The federal-state-local layering of governments in the United States and the relationships among the many semiautonomous state governments have long posed questions of substantial moment and perplexity to fiscal economists. Attempts to come to grips with these issues have resulted in a reasonably large body of literature, varying in degree of theoretical, empirical, and institutionally descriptive emphasis. Professor Musgrave's own contributions to what might be called federal and multiunit fiscalism utilize these three approaches, sometimes in amalgam and sometimes in pure form, and of course his studies are justifiably noteworthy. The present volume of five essays is yet another dimension of Musgrave's intellectual fecundity, insight, and enterprise, each of the pieces being based upon a doctoral dissertation written under his tutelage. That these five dissertations were filed within the short span of three years at Johns Hopkins and Princeton, whose outputs of economics Ph.D.'s are on a relatively small scale, is vivid testimony to Musgrave's effectiveness as a teacher and nurturer of scholarly activity. The volume, moreover, must be reassuring to the National Committee on Government Finance whose "seed money" has so conspicuously and handsomely paid off.

It is not intended that this merited praise of Musgrave should spread a shadow over the five young economists whose work the volume presents. Quite the contrary. Each of the essays displays a cast of research design, a faculty with empirical data, an inventiveness in hypothesis testing and a caution and refinement in interpretation of results that are sufficiently distinctive to allay the fear occasionally arising with dissertations that the imprint of the mentor is overriding. On this volume's demonstration the Musgravian imprint is delicate and subtle, as it should be. The essays offer a fortunate blend of the theoretical, institutional, and empirical, to be sure; but without doubt the work reported in these essays is truly independent and of a caliber infrequently found in the research of more mature economists. These essays, moreover, must be read if one is to appreciate the refreshing qualities of the research effort, and no statement of short compass could convey these qualities with a semblance of justice. It is possible to relate a few of the more tangible and salient results of the essays. This will indicate the primary focus of the individual studies; the logical inference that the volume contains other interesting and related points is quite proper.

Two of the essays are concerned predominantly with stabilization policy in a federal and multiunit political system. Stanley Engerman's study reveals a high conformity of postwar business cycles in the several states with those at the national level. But while the turning points are largely coincident, the amplitudes of the swings vary appreciably among the states. This suggests that stabilization policy should, in some instances, be regionally pin-pointed and, through a rudimentary application of input-output studies, Engerman shows that this would be an effective strategy. He contends, moreover, that regional

stabilization policy must be the responsibility of the federal government since the causes of regional differentials in, say, unemployment rates are national in character. These conclusions are based on an analysis of annual data; apparently seasonal adjustment problems precluded the use of quarterly series. Within this constraint, however, Engerman's arguments are well supported. Our stabilization experts can ill afford to overlook them, particularly when national employment is full or when regional pockets of heavy unemployment are known to exist.

The other essay on stabilization policy is by Robert Rafuse. He tests for the postwar period the validity of the so-called "perversity hypothesis"—that the behavior of state and local tax receipts and expenditures exaggerates rather than damps business cycles. The most prominent feature of postwar state and local outlays is their rapid and virtually continuous rise. This largely accounts for the destabilizing nature of receipts during downswings and of expenditures during upswings. When the effects of growth are eliminated, expenditures become stabilizing during both expansions and contractions. Receipts, while not yet countercyclically stabilizing, have tended to become less destabilizing with the passage of each cycle, reflecting the increasing income elasticity of tax yields as the relative shares of the various taxes in the aggregate of state and local receipts change through time. The *net* cyclical impact of these forces is that state and local fiscal behavior is highly countercontractionary but also proexpansionary. This proexpansionary aspect need not necessarily weigh against state and local governments since it is not wrong to abet upswings *per se*. Moreover, as Rafuse demonstrates, the net proexpansion fiscal impact tapers off in the later stages of the upswing, reinforcing the possibility that the total stabilization performance of state and local fiscal behavior is on the whole beneficent. These comments do not reflect the nuances of Rafuse's analysis; they indicate, however, that the "perversity hypothesis" is a gross oversimplification.

An estimate of the over-all incidence, by family income class, of federal, state, and local expenditures and taxes is the major consequence of Irwin Gillespie's study. Since the incidence of tax receipts has already received much attention, he rightly concentrates his efforts on measuring the impact of the various types of expenditures. His results unavoidably depend upon his assumptions concerning the allocation of particular expenditures; and while one may quarrel with some of these there is little prior work to rely on. Given his assumptions, Gillespie's method derives for 1960 the gain or loss by income class, as a percentage of income, owing to federal taxes, expenditures, and the net budget pattern, on the one hand, and owing to state and local taxes, outlays, and the net pattern, on the other, and finally combines these into an all-government impact. He finds, as a capstone measure, that the net pattern stemming from state and local government budgets is beneficial to income classes below \$4,000-\$5,000 i.e., pro-poor, and relatively neutral for all higher income brackets. The net pattern at the federal level, while somewhat less pro-poor, becomes anti-rich at incomes above \$10,000, with neutrality maintained in the intermediate range. The all-government net budget pattern exhibits a

substantial pro-poor impact for the lowest income class, falling rapidly to neutrality at the \$4,000-\$5,000 income bracket, sustaining neutrality through the \$7,500-\$10,000 bracket, and becoming anti-rich at family incomes in excess of \$10,000. In short and too simply, families with 1960 incomes greater than \$10,000 were subsidizing, through federal and state and local fiscal processes, families whose 1960 incomes were less than \$4,000. To most economists, these will be gratifying findings. Perhaps, had it been possible for Gillespie to utilize a breakdown of income classes beyond the \$10,000 level, less comforting results would have been obtained.

One of the recent issues of tax equity—the treatment of state and local taxes for purposes of computing the federal individual income tax—is explored by Benjamin Bridges. Is it desirable, he inquires, to maintain the current practice of full deductibility of virtually all of state and local nonbusiness taxes, or is some other form of allowance, such as a credit against federal taxes, or even of complete “nonallowance” preferable? On equity grounds, Bridges recommends elimination of the deductibility provision, but suggests that as an aid to state governments it may be expedient to permit state personal income taxes to be credited against federal tax payments and that all other nonbusiness taxes should be nondeductible. In arriving at these proposals, Bridges examines on the basis of 1958 figures the prospective change in the federal tax take, the impact on state and local tax revenues, the effect on tax progression, the consequence for interstate income tax differentials, and other outcomes of seven hypothetical deduction and credit plans combined with several reaction patterns from state governments. Bridges’ exploitation of the data is imaginative and painstaking. Aside from his general recommendations, one of the more provocative demonstrations is that with the present deductibility provisions interstate income tax differentials are quite small compared to the net income of the taxpayer; tax differentials are not apt to be a significant determinant of place of residency or employment.

The final essay is William Birdsall’s attempt to specify the determinants of demand for public goods. He recognizes that he has probably failed to establish the factors underlying demand, as distinct from preferences: rational calculation of future benefits and costs of public goods is extremely difficult, and evidence suggests that these calculations are frequently not made. In the absence of this, no technique can capture the elements of demand. Yet, Birdsall seeks the determinants of preferences for public goods in a novel way. Voting results on 26 financial referenda in 55 New York communities are regressed against a sizable number of salient variables. Though it is not Birdsall’s fault, the results are disappointing. With few exceptions, the *a priori* relationships between the various voting results and their presumed explanatory variables are not supported. This was true whether the explanatory variable in question was thought to be a “general” determinant of voting behavior or a “specific” determinant of the vote on a particular type of referendum. Nevertheless, a study of this sort needed to be done; it is to Birdsall’s credit that he has pursued all potentially constructive possibilities in this pioneering effort.

The foregoing remarks suggest that the volume is extremely provocative. Many of the conclusions are real eye-openers; the data are masterfully ex-

ploited; the results are thoughtfully analyzed. The volume—and each of its essays—is a significant contribution to stabilization policy and fiscal economics.

M. O. CLEMENT

Dartmouth College

A Capital Budget Statement for the U.S. Government. By MAYNARD S. COMIEZ. Washington: The Brookings Institution, 1966. Pp. xv, 143. \$6.00; paper, \$2.50.

Federal finances include many and large transactions which in one respect or another extend well beyond a single year, e.g., loans, repayments, and outlays for construction. The budget, however, lumps such "capital" items with the "here today and gone tomorrow" outlays for current operations. True, budget presentation has been elaborated to include special accounts for some capital items. Yet the budget figures which seem to bear most directly upon decision making, and certainly those getting public attention, mix items for the shortest of the short run with figures for transactions which will not be fully liquidated before our grandchildren run the country.

Federal practice differs from that of business and many state and local governments. Must not federal procedures be defective? Failure to allow for (large) differences in the time element of economic actions must lead to avoidable errors. Numerous economists, myself included, have asserted that federal budgeting for capital transactions has weaknesses which could be reduced. Perhaps a separate capital budget would help. Lack of evidence about magnitudes, however, has hampered meaningful debate.

Now we have magnitudes for the years 1955-63, thanks to Dr. M. S. Comiez of the U.S. Bureau of the Budget. His study, one of the Brookings *Studies of Government Finance*, is in no sense "official," but it does not conclude with advocacy of sweeping change of present practice.

The book opens with a brief discussion of concepts, including reasons for doubting that "durability" and "tangibility" of results are a necessary test of "investment" by government. A short historical background closes the introduction. The 16-page chapter, "An Appraisal of Capital Budgeting," could stand by itself as an excellent summary of the theory and issues. The author rejects the argument that the federal government should have a capital budget just because businesses do; the fundamental objectives of business and government differ profoundly; some of the ends which we seek through government cannot be related to anything like the profit-maximizing which business accounting seeks to serve; the federal government's ability to borrow does not depend upon its balance sheet (assets) nor upon earning capacity in a sense comparable to that of a business firm. To apply "a concept of financial soundness for the private business world" (p. 19), he concludes, would be a backward step in getting a better comprehension of the respects in which the federal government and business are different types of agencies for achieving different types of ends.

Would the acquisition of long-lived assets be wiser if capital items were segregated from current expenditures? The author finds little reason to expect

improvement. Both accrual accounting and the explicit calculation and statement of depreciation may help in planning maintenance expenditure and replacement. Yet as regards the cost information needed for efficient management and control, "A cost-based budget system of accounting for individual projects and activities satisfies the need for such information without separate treatment and financing of capital outlays in the national budget" (p. 21). Would a capital budget help produce better public understanding of the difference between expenditures for current operations and capital outlays? The author concludes that a generally satisfactory alternative can be found in the expansion of special exhibits.

Would separate capital budgeting of capital facilitate better planning of capital outlays? If construction projects were associated with loan financing, would we not decide more wisely than today when the cost is a charge on current taxes? After examining pros and cons, the author says "No." The year-to-year demand for taxes would change very little. To relate capital spending to loan financing with either an explicit charge for depreciation or some provision for self-liquidation might help improve the balance between present and future generations—but not much. Conceivably, but not certainly, the use of loan financing rather than taxation might help to decide more wisely which investment projects to undertake.

Countercyclical fiscal policy would become much more difficult if loan financing and capital expenditure were associated closely. The amount of borrowing or debt repayment desirable for countercyclical policy has no necessary relation to the needs for new federal facilities or to depreciation on those in existence. Although loan financing of capital projects might encourage the substitution of user fees for taxes and in some cases bring better balance between present and future generations, the distribution of costs between users and nonusers might become less desirable. Finally, resource misallocation could be encouraged—capital projects of government might get more relative to either current account or private investment than justified; investments in "human capital" might be slighted if outlays on health and education were expensed while bricks and mortar were capitalized; items of current expense might be shifted to capital account to disguise the true total of operating costs.

The author concludes that a formal capital budget is not needed for the classification essential for planning government spending, for cost analysis, and for measuring federal finances as part of the national accounts. Efforts to improve present methods should continue, e.g., in allowing for depreciation and probable loan losses, but within the present type of unitary budget.

The analysis gives little attention to capital transactions of a more exclusively financial nature. The author does not, for example, discuss the significance of that current "growth phenomenon," the sale of financial assets (loans) to finance current spending, with the budget totals reflecting only the net difference. Nor does he deal with the problems of measuring federal assets for inclusion in estimates of national wealth.

Chapter 3 summarizes the empirical study. Five chapters then deal with major topics, including the definition of capital expenditures and receipts, cal-

culatation of depreciation, treatment of various types of defense spending, and the development of a capital budget on a consolidated cash basis. Seven appendixes with 31 tables present greater detail on statistical sources and methods, and on findings.

"Civil capital" includes loans and investments, public works, changes in major commodity inventories, and major equipment and other physical assets, all limited to the federally owned. The receipts which are treated as offsets are loan repayments and proceeds from sales of property. The net excess of civil capital expenditures over offsetting receipts ranged from \$1.4 (1957) to \$7.0 (1959) billion.

The computation of depreciation and of loss on loans and inventories rests upon a variety of assumptions; but they appear reasonable. The 1955 figure was \$1.2, that for 1963 \$1.5, billion. In five out of nine years losses on commodity inventories were over 40 per cent of the total. If depreciation is limited to assets acquired after 1955, the totals drop to \$700 million in 1963. National defense capital expenditures, including both public works and major military equipment (aircraft and ships), ranged from \$8.0 (1961) to \$10.3 (1958) billion.

Five models employ the administrative budget concept, two the consolidated cash budget. One of each group seems to the author clearly most appropriate. The first (Case II) adds net civil capital, as noted above, to the administrative budget and then deducts depreciation and losses on loans. How do the results compare with the official figures? Deficits are smaller in the six deficit years and surpluses are larger in two of the three surplus years; in no case is a deficit converted into a surplus. But some differences justify the author's characterizations as "significant"—the 1959 deficit of \$12.4 falls to \$6.7 billion. For the nine years the cumulative deficit drops from \$31.5 to \$12.2 billion. The two models which include certain national defense outlays as capital spending show cumulative surpluses of \$20.8 and \$26.4 billion, rather different from the \$31.5 deficit in the official figures.

The second of the preferred models (Case VII) is essentially Case II based on the consolidated cash budget to take account of trust fund transactions and government-sponsored enterprises. Federal outlays for the interstate highway program are not included, however, because the highways are not federally owned. The taxes earmarked for highways are treated as capital receipts on the same basis as receipts from loan repayments. Surpluses become larger, deficits smaller, but in no year does one become the other. The cumulative deficit as reported officially, \$22.1 billion, drops to \$2.0 billion.

The author did not set himself the task of trying to judge how much, and in what ways, decisions might have been altered if capital budgeting had been used. As one looks backward, the difference in deficit or surplus in most years does not seem large in relation to other magnitudes. But who can be sure about the effect on decisions? Depreciation appears much smaller in total than casual impression might have led one to expect. If the federal government had a balance sheet, the net position would have appeared about \$19 billion better in 1963 if capital budgeting (Case II) had been used over the nine years.

Perhaps among the problems of federal finance those of capital accounting

are of much lower order of priority than some of us had thought. This book leaves such an impression. Comiez has not attempted to cover all the issues. He has, however, provided estimates which will help in sharpening our analysis. Whether pleased or dissatisfied with present practices, all of us can now direct attention more fruitfully because measurement rests on a firmer foundation.

C. LOWELL HARRISS

Columbia University

Program Budgeting—Program Analysis and the Federal Budget. Edited by DAVID NOVICK. Cambridge: Harvard University Press, 1965. Pp. xvi, 382. \$6.50.

Very few volumes on public policy have been better timed than this one. On August 25, 1965, President Johnson announced at a news conference the introduction of "a very new and very revolutionary system of planning and programming and budgeting throughout the vast Federal Government." Fortunately, David Novick and his associates had in manuscript a book on program budgeting, the product of a RAND-sponsored project that had been initiated about two years previously. Whereupon an abridged version of the manuscript was offered to the Government Printing Office and published in the early fall. The present volume, which contains three additional chapters, was published in December.

On October 12 the Bureau of the Budget, in implementation of the President's announcement, issued a bulletin (66-3) establishing the planning-programming-budget system (PPBS). In accordance with the October bulletin, 23 major federal departments and agencies are to prepare their 1968 budgets in program categories. An additional 17 agencies are "encouraged" to adopt PPBS.

The conceptual basis for program budgeting dates back to the Taft Commission on Economy and Efficiency in 1912. Applications started with the New York Bureau of Municipal Research in its budget for the borough of Richmond in the years 1913-15. In the federal government TVA and the Department of Agriculture developed a program budget format in the 1930's, as did the Navy Department in 1946. The Hoover Commission recommendations of 1949 and 1955, which urged the extension of program and performance concepts to other departments and agencies, were thus built on a record of existing but modest federal effort.

The immediate historical antecedents are, of course, RAND, Charles J. Hitch, and Secretary Robert McNamara. Beginning in 1961, the program budget, with accompanying techniques for military planning, became a major device to revolutionize the Department of Defense, integrate the services, centralize decision authority in the hands of the Secretary and his immediate staff, and impress the Congress. It must follow that what is good for Defense is good for the civilian agencies.

And it may all be true; the present volume is persuasive. Certainly no economist can object to the introduction of additional economic content into the

budgetary process. The task is to assure that narrow efficiency values do not dominate all other considerations.

As the authors point out, the traditional line-time budget classifies government expenditures (and obligations) solely in terms of inputs—the things that are bought. A program budget classifies in accordance with outputs and the resources necessary to yield a specified output. Resource costs are carefully measured to facilitate incremental analysis. The time dimension is extended beyond the immediate fiscal year, to permit a projection of the future consequences of present decisions. A program structure accommodates cost-effectiveness studies that may be used to evaluate alternative means of accomplishing objectives.

This sounds rather simple, and, in fact, is reasonably straightforward in some areas. The chapters by Novick on the Department of Defense and by Milton A. Margolis and Stephen M. Barro on the space program demonstrate this. But for civilian programs it is most difficult budgeting.

The chapters by John R. Meyer on transportation, Werner Z. Hirsch on education and natural resources, and Marvin Frankel on health are generally realistic in pointing to the problems. The central difficulty lies in the multipurpose nature of government activities. Transportation expenditures serve both national defense and civilian needs. The armed forces have large outlays for education and training. Expenditures for the abatement of air and water pollution serve both natural resources and health. Programs for medical research could be either education or health or both.

The authors of both the general chapters and the chapters on applications consistently point out that there is no single best classification but suggest that most of the difficulties can be resolved by a "translation grid" that will link existing classifications with new ones. It is not possible, as most of the authors recognize, to undertake an administrative reorganization in the interests of program budgeting. If a purely functional approach were simple, we would long ago have had federal departments of transportation, education, and water resources. In the absence of administrative reorganization a great many programs will cut across agency and departmental lines.

It follows that program budgeting becomes a technique, not for management at the operating level, but for the centralization of administrative authority. The technique is not, as Melvin Anshen would have us believe (pp. 15, 370), a "neutral instrument" with no "politics." It will upset existing budgetary decision patterns by transferring authority from bureaus to departments. It will strengthen the Executive Office of the President in dealing with both departments and agencies and in negotiating with the Congress. It will determine, for example, that school lunch programs should be viewed as education programs and not as health programs or as agricultural surplus disposal programs. Thus the education budget will appear to be larger or smaller in accordance with the classification that is adopted. Classification decisions of this sort, as Hirsch points out (p. 198), might amount to as much as \$1.0 billion in an education budget of \$3.6 billion. These are political decisions in any meaningful sense of the term.

Program budgeting will certainly be helpful in making decisions about alternative means of attaining specified and agreed-upon objectives. It will be of very little use in illuminating the values that must underlie choices among programs, as most of the authors agree. The best measurements of costs and outcomes will not reveal whether it is better to spend on highways than on health, or on education for suburban children rather than on education for children in slum areas. Program budgeting will not carry us very far toward the Pigovian ideal of distributing expenditures toward battleships and Poor Relief " . . . in such wise that the last shilling devoted to each of them yields the same return of satisfaction" (*A Study in Public Finance*, London 1951, p. 31).

As Arthur Smithies says, in his realistic chapter in this volume, "The idea of economic measurement has great attractiveness because of the analytic possibilities that it offers, especially to economists. But it is a perversion of human values to push it into areas in which it does not belong" (p. 51).

JESSE BURKHEAD

Syracuse University

Federal Budget Policy. By DAVID J. OTT and ATTIAF F. OTT. Washington, D.C.: The Brookings Institution, 1965. Pp. xiv, 150. \$5.00; paper, \$1.95.

When President Kennedy was having difficulty in 1963 arousing public enthusiasm for tax reduction to stimulate business, he is reported to have asked, in effect, "Where are all the people who have taken 'Eco 1' since the war?" Economists may not have done well in their educational efforts—or perhaps the job far exceeds our resources. In any case, public "discussion" of recent years demonstrates the need for more professional effort in explaining the economic aspects of public policy issues. This smallish book, one of the *Brookings Studies of Government Finance*, attempts, with considerable success, to present both facts and argument needed for nonprofessional understanding.

"Primarily educational," not a report on empirical research or new theoretical inquiry, this book ranges far beyond "policy" in the ordinary sense. College teachers of economics will find it useful even though much duplicates what appears in many textbooks. Students of government, sociology, and social studies—the "man of affairs" in business, government, or the professions—should also benefit, but not without some difficulty.

A concise summary of budget concepts—administrative, cash, and national income—precedes a 23-page description of the budget process from executive preparation through Congressional authorization to post audit. Both the factual account and the authors' evaluations suggest direct contact with the executive branch, giving a flavor of "telling from the inside." Ten groups of postwar improvements are identified, all in the executive branch. Congress gets credit for a few attempts to improve the handling of its part of the job, but for almost no accomplishment.

Tables, charts, and brief text summarize the record of federal taxes and spending from various dates to 1964. Actual receipts and expenditures often differ considerably from the estimates; the authors account (apologize?) for

disparities without pointing out the significance for public policy of our inability to count upon forecasts of federal finances.

Chapter 5 goes further than the "typical" elementary presentation of the (aggregative) effects of federal expenditures and taxes on employment and prices. After showing why the price level tends to rise before all but frictional unemployment disappears, the authors conclude that society may be able to get the desired combination of employment and price-level objectives only by "a weakening of union powers or a decrease in business monopoly power, or by stronger or weaker policies on the part of government to affect prices and wages" (p. 59). Discussion of the job-prices dilemma suffers from one large but unnecessary omission. Why not make clear that the man-hours of employment which any given aggregate dollar demand—say \$700 billion—will buy depend upon the average wage rate per hour, more employment if the average cost of the employer is \$3.50 than if it is \$4? This relation bears upon the longer-run employment effects of increases in wage rates and the possible need for fiscal action.

The treatment of economic processes and relationships takes account of such variables as different lags and liquidity effects—but not monetary action. A tone of realism, the modesty of the claims about what can be counted upon, might well have received more cross-referencing later. The attempt to develop "refinements," I fear, is not entirely successful. For example, in explaining why the deficit or surplus is an inadequate measure of fiscal action, the authors (a) distinguish between intentions and results and (b) point out that the results which are realized combine those of automatic stabilization with those of discretionary policy. Many a reader who does not already understand will need more explanation (or none?).

The presentation of the economic aspects of alternative budget policies combines points long familiar to economists with some which represent more recent analysis. "There's more than meets the eye" in condensed discussions of the inadequacy, or worse, of annual balance as a guide, of the CED automatic stabilizing plan, and of formula flexibility. The first choice of the authors is a mixture of policies. For the longer run they prescribe discretionary policy which puts heavy reliance upon tax rate adjustments (probably at three- to five-year intervals); expenditures would be determined on the basis of the merits of each program. To the extent that fiscal action is to be used for moderating short-run fluctuations, reliance would be placed on automatic stabilizers. In a few pages the authors bring to the reader major fruits of masses of professional study.

Those of us with some experience in trying to explain "modern" fiscal policy to noneconomists know that there is no escaping queries and worries about the national debt. The authors explain the concept of public debt and the error in figures of federal obligations reaching \$1 trillion or so. Less successful, however, are the sections dealing with burden of debt; a digest of recent journal debate on debt burden calls for considerable background. How many readers in the intended audience will comprehend what the authors say about points which professional economists may not yet have stopped debating?

The final chapter, "Determining the Need for Federal Spending," deals

with considerations other than those of employment, price levels, and growth. When many points of diverse nature appear—while others which one believes should appear are missing—a reviewer cannot comment in detail. The authors allot three pages to evaluating the forces which influence the division of government spending between federal and state-local. Three topics—spending on public goods, spending to affect income distribution, and spending on semipublic goods—each receive two pages. A section, "Some Common Fallacies in Judging Federal Spending," makes some good points well. The chapter as a whole, however, suffers from oversimplification or, rather, overambition. Much of what appears will be helpful for the intended audience. The net result, however, is disappointing; the subject is too vast for a few pages.

Four short appendixes include nine tables of statistics, two discussions of derivation of concepts, and an excellent bibliography.

The book's weaknesses result primarily from an attempt to do more in terms of topics covered and depth of analysis than proved do-able. But having just criticized overambition, I reveal the hounding complexity of the problem by adding that the total result suffers from the self-imposed exclusion of monetary policy. The merits are more impressive. They result from a combination of professional competence and willingness to work to "let the people know." The total effectiveness is enhanced by another combination—an evident determination to be judicious where controversy is involved, while taking positions and supporting them.

This is a book of which one can say, "The wider the readership, the better the prospects of American society."

C. LOWELL HARRISS

Columbia University

Financing State and Local Governments. By JAMES A. MAXWELL. Washington: The Brookings Institution, 1965. Pp. xvii, 276. \$5.00.

At a moment in fiscal history when state and local spending on goods and services gives indication of outpacing federal spending, *Financing State and Local Governments*, by James A. Maxwell, is a well-timed and exceedingly thorough analysis of the facts, problems, and policy implications of financing lower levels of government in the United States in the 1960's. The volume is the tenth publication in the Brookings Institution series of *Studies of Government Finance*.

Maxwell places his subject in historical perspective. In doing so, he illustrates the significant diversity in state systems of taxation; at the same time his work illustrates the historical status quo which has existed in local public finance as manifested by the dominance of the highly inequitable, administratively cumbersome, and fiscally ineffective property tax.

His subject matter is organized sequentially along the following lines: The stage for his major task is set by an historical chronology of intergovernmental fiscal relationships under the federal system. Next he reviews the pattern of expenditures, relative revenue generating efforts, and patterns of tax preference in state and local units of government. The role of intergovernmental transfers receives a thorough treatment. Two chapters are devoted to a factual

review and comparative analysis of state individual income, sales, and other taxes; as might be expected, most of the discussion of local taxation is concerned with the property tax and the manner in which it might be rehabilitated; other subject areas are the state and local debt picture, the earmarked-revenue concept, capital budgets, and future trends in state and local finance in the United States. A wealth of factual data is incorporated into a series of appendix tables. These are invaluable reference sources, particularly the tables which present comparative data by state on expenditure and revenue patterns.

This reviewer is in full accord with Maxwell's analysis of and recommendations on the state-local system of finance, with one major exception. Maxwell and I hold diametrically opposed positions concerning the equity, the administrative feasibility, the fiscal efficacy, and the compatibility of the local property tax with the public finance requirements of an urban-industrial society.

Maxwell asks (p. 129), "should a renewed effort at reform be made? Is the property tax worth refurbishment?" He replies in the affirmative primarily in the belief that "local governments should have a major source of revenue of their own." Here we part company. My position is that the property tax should be gradually phased out of the modern local revenue system. The tax is simply incompatible with the fiscal needs of an urban-industrial society.

In appraising the economic and equity effects of the property tax, Maxwell concludes (p. 133) that "the property tax cannot be awarded a high position." Yet he manifests an element of fiscal fatalism when he observes (p. 133), "But no alternative *local* taxes are in sight."

Most students of public finance believe that the property tax is highly regressive when related to the income position of the taxpayer. Maxwell, on the other hand, refers (pp. 131-32) to Musgrave's 1954 data (p. 398) to Margaret G. Reid's *Housing and Income* (1962), and (pp. 298-308) to the Survey Research Center, University of Michigan, *Income and Welfare in the United States* (1962), and concludes that the "regressivity belief" is of questionable validity. He suggests, further, that improved assessment procedures since 1954 have moved Musgrave's figures on the pattern of property tax regressivity toward proportionality (P. 131).

My own empirical studies of the pattern of distribution of property tax burdens in California indicate a high degree of regressivity. For example, a sample of 1,300 completed questionnaires of 5,000 households in a California community of 20,000 persons revealed that the family units with \$2,000 annual income had annual property tax burdens ranging from 10.0 to 45.0 per cent of household income. The median burdens in the \$2,000 and \$10,000 income groups were 15.0 and 5.0 per cent, respectively. Musgrave's 1954 data suggest effective rates of 4.2 and 3.2 per cent for these income groups in the United States. Clearly, the 1954 data do not provide the factual framework within which to appraise the equity of the local property tax in the decade of the 1960's. The conclusion that the local property tax trends toward proportionality merits large scale empirical analysis.

One further aspect of Maxwell's analysis of property taxation should be mentioned. In discussing the property tax base he argues (pp. 133-34) that the inclusion of both intangible "representative" property, i.e., stocks, bonds,

mortgages, bank deposits, etc., and the real property on which the representative property rests, is clearly duplicative. Here we have the familiar "double taxation" argument. Maxwell's analysis is in keeping with the conventional wisdom, but it abstracts from such realities as the separation of ownership and control and the relatively independent legal, economic, and social status of the corporate entity, per se, in modern society.

Let me hasten to add that the volume is an exceedingly valuable contribution to the field of public finance. I recommend that the book be used as a second required text in general courses in government finance. It fills a long-deficient reference need for students, scholars, and practitioners at a time when the problems of state and local finance are on the ascent.

GERHARD N. ROSTVOLD

Claremont, California

The Public Economy of Urban Communities. Papers Presented at the Second Conference on Urban Public Expenditures, Held February 21-22, 1964, under the Sponsorship of the Committee on Urban Economics of Resources for the Future, Inc. Edited by JULIUS MARGOLIS. Washington: Resources for the Future, Inc.; Johns Hopkins Press, distributor, 1965. Pp. xvii, 264. \$5.00.

In his introduction to this volume of papers Professor Margolis sees the thread that ties them together in the nature and evolution of the "new field of public economics." Public economics is "A full-fledged economic analysis of government as a producer of goods and services and as the sovereign setting the rules of economic and social organization." If one is inclined to define public finance in terms of the contents of the standard American text book, then Margolis is indeed justified in his call for recognition of a new "field." But the case is far less clear when viewed in the light of the work of Pigou, the scholars of continental Europe, and in this country such people as Musgrave, Samuelson, Buchanan, Harberger, Shoup, among others, whose work surely involves "public economics," even if we have always called it "public finance." The latter term may well be misleading, but even more confusion seems inherent in the effort to move away from it toward the definition of a new subdiscipline which must include most of what economists generally think of as public finance while merely adding a few analytical tools and areas of analysis to the traditional ones.

Irrespective, however, of whether one prefers public economics or public finance, at least three of the papers contained in *The Public Economy of Urban Communities* appear, at best, to have only a very remote relevance for either public economy or urban communities. Professor Rothenberg builds a formal model of political behavior out of the notions of demand (from citizens) for and supply (by legislators) of "political support." Apart from an interesting analysis of types and compositions of political coalitions, however, his paper offers little that seems to promise new insights for understanding the public sector. Granted that "long-run welfare criteria" would be handy to have, Harvey Leibenstein, despite a valiant effort, gets hung up, not unexpectedly, on the intergeneration problem. Since unborn generations clearly have no

discernible preference functions, we have in his paper some ably put questions, but hardly the empirical basis for welfare decisions that he seeks. The third in this group of contributions, "Majority Voting and Alternative Forms of Public Enterprise," by Benjamin Ward, contains nothing, beyond some introductory remarks, that is specific to *public* enterprises. It focuses, rather, on decision-making by variously constituted boards of directors through alternative voting procedures.

The other eight essays are both less ambitious and more relevant to the subject matter suggested by the book's title. Professors Buchanan and Tullock develop an interesting analysis of public and private adjustments to the existence of reciprocal external economies associated with a variety of activities that may be undertaken either privately or collectively or both privately and collectively. Their showing that public provision of a good the consumption of which involves major external economies may not, indeed is unlikely to, yield Pareto-optimal results is not surprising. Their analysis, however, constitutes an important contribution to the theory of public finance.

James Q. Wilson and Edward C. Banfield examine the hypothesis that, in elections authorizing expenditures for various local public projects, voters tend to behave in a manner suggesting the pursuit of self-interest. They find that in the larger cities low-income renters "almost invariably support all expenditure proposals," but that for higher-income groups self-interest appears to be replaced by a "public-regarding" attitude, particularly among Anglo-Saxons and Jews. Their results, based on voting records and population characteristics by precincts, seem more than sufficiently promising to warrant further research along similar lines.

Otto A. Davis sets up a model of "political influences" on public school expenditures per pupil in a six-county area of western Pennsylvania. He then proceeds to a presentation of the results of multiple regression analysis in which the statistically significant predictor variables turn out to be the proportion of the electorate owning property, per capita market value of taxable property, and the proportions of children attending public and nonpublic schools. Whether or not these variables represent political influences may be debatable, but there appears to me to be little call for Davis's conclusion "that economists attempting to understand this [allocation] process would do well to discard at least a part of their notions of demand and supply and, hence, the implicit implication that a pricing mechanism is the allocation device in the public sector." Surely some economists, if not Davis, are familiar with the efforts of those of us who have done just that, including Werner Hirsch, Jerry Miner, and myself, among others.

The paper by Professor Weisbrod is drawn from his *External Benefits of Public Education*. It presents a crude but interesting effort to test the hypothesis that benefit spillovers associated with local expenditures for education lead to reduced educational outlays and a shift in financial responsibility to higher levels of government.

Allen V. Kneese, in a succinct, well-reasoned paper, offers an excellent treatment of the economic issues in decisions regarding water quality control. He makes a convincing case for the need for a great deal more effort on the

part of economists than has been forthcoming in one of the most important public policy areas facing industrial communities everywhere.

Using the case-study approach, Nathaniel Lichfield succeeds in clarifying the issues involved in the employment of benefit-cost analysis in choosing among alternative plans for urban development or redevelopment. Problems of measurement of benefits and costs and identification of repercussions of alternative projects are well illustrated, as is the importance of detailed specification of "instrumental objectives."

Far too large a part of the paper by Benjamin Chinitz and Charles M. Tiebout is devoted to a restatement of Musgrave's three-part budget system and his classification of public goods as social-want and merit-want satisfying goods. This taxonomic scheme contributes little or nothing to an understanding of "The Role of Cost-Benefit Analysis in the Public Sector of Metropolitan Areas." It is no wonder, then, that the theoretical analysis falls down at an early stage and the authors conclude only that the application of cost-benefit analysis "is not at all easy, even at the conceptual level." And while the brief discussion of "cost-benefit analysis and the allocation of transportation" points up well the economic issues involved in metropolitan transportation problems, it tells us very little about the role of cost-benefit analysis in the solution of these problems.

Finally, Professor Strotz's "Urban Transportation Parables" are spelled out in the form of mathematical statements (not all of which I can follow, I readily confess). They lead to such conclusions as "Thus, population density should tend to fall off the further land is from the city center . . ." and "... a stretch of road should be taxed, subsidized, or be exactly self-financing depending on whether returns to scale of the congestion function are adverse, favorable, or constant. . . ." These conclusions hardly seem new, but there may be useful reassurance to be found in the elegance of the demonstration of their validity.

Clearly it has been impossible to do justice here to eleven papers covering an extremely wide range of topics. I find it difficult to identify a theme or unifying thread running through the book, and the title hardly seems descriptive of its contents. The specialist in public finance will find several of the contributions well worth reading, while others are best skipped, and many other readers will discover, perhaps to their surprise, that they have long been engaged in research in "The Public Economy of Urban Communities." On the basis of my own tastes I would suggest that the benefit-cost ratio will probably exceed 1 for those who confine their reading to the papers by Buchanan and Tullock, Wilson and Banfield, Kneese, Weisbrod, and Lichfield.

International Economics

International Monetary Relations—Theory, History, and Policy. By LELAND

B. YEAGER. New York: Harper & Row, 1966. Pp. viii, 504. \$10.50.

Professor Yeager provides us with a long and generally excellent book on

"international finance." International finance is, to some of us, empirically the most pertinent portion of "international economics." (Even in matters with a "commercial policy" context, the issue can be largely "financial," as in the question of optimum currency areas, touched on lightly by Yeager, pp. 98-99, 487.) Recent reviews of the theory of "international trade" make apparent the embarrassingly precious quality of much of that theory and the considerable extent to which it has moved in effect toward objectives other than explication of the world. Yeager not only has chosen the more substantial sub-area but has devoted his exposition to elucidating the subject rather than to confounding us with ingenuity in doodling.

The volume is in two parts of equal length: "theory" and "history and policy."

After an opening chapter which provides a summary primer of trade theory and is virtually unutilized later (thus illustrating the considerable gulf between "trade" and "finance") and a second chapter which surveys selected techniques and technicalities of the foreign exchange market, the first major topic is the balance of payments. Alternative approaches to defining and measuring equilibrium are sketched; Yeager's orientation on the mechanics of this problem centers on the admittedly difficult notions of "independently motivated" and "compensatory" transactions (pp. 46-47), but he well emphasizes the status of individual economic units and their connection with the central bank in interpreting the meaning and significance of a payments deficit (pp. 51-53). The remainder (10 chapters) of Part I is devoted to the theory of balance-of-payments adjustment under pegged and fluctuating exchange rates and under direct controls, along with repercussions of adjustment on the terms of trade and the price level and the nature, importance, and possible control of speculation. The three chapters on speculation and related matters constitute one-quarter of the first part.

In Part II, there is a history of monetary standards before World War II (4 chapters); wartime experience and planning and the IMF (2 chapters); postwar evolution to convertibility and case studies of England, France, Germany, and Canada (5 chapters); dollar shortage and glut (1 chapter); and existing "liquidity" arrangements and reform proposals (3 chapters). In these hard-headed discussions, some profane—and perhaps some near-sacred—toes are firmly trod upon.

The volume is large: almost 500 oversized, double-columned pages, including seven end-of-chapter appendices comprising 28 pages of small print. There is no consolidated reading list, but the footnote-citation items would constitute an impressive (but not exhaustive) and well-selected bibliography. Often the discussion is commentary, assessment, and elaboration of the literature (always sensible and frequently subtle) more than systematic, comprehensive exposition; it is almost as much high-level critique and monograph as textbook. It probably warrants comparison with Meade's major opus more than with the lesser books—useful in their ways—by Henning, Wasserman-Hultman-Zsoldos, and Ward.

For all of the bulk, the saneness, and the erudition of the work, it is lacking in extensive, detailed presentations on a few key matters and conspicuous

items of literature, e.g., measurements of payments imbalances (there is no explicit reference to relevant works of Lederer, Høst-Madsen, or Lary and little to Gardner), the Hicks differential growth model (briefly noted, pp. 459-60), stability conditions with initial payments imbalance (p. 158, n.), the Domar analysis of international investment and balance-of-payments stages (not mentioned). Again, one may be dubious, at least from the student's point of view, that justice can be done to some expositions of internal-external equilibria (e.g., Mundell, Hemming-Corden) and of devaluation without a bit of geometry; or to the absorption approach without employing income equations; or to the mechanics of the foreign-trade multiplier without considerable algebra or "period" tables. In addition, there are, quite inevitably, a few places where one may have some doubts on judgment or emphasis, and infrequently the exposition is a little austere or not as simple as it could be (e.g., some of the algebraic derivations, while systematic, are admittedly tedious and not always the easiest presentation).

But while the discussion may occasionally slip between the two stools of "monograph" and "textbook," such difficulties are greatly overbalanced by the impressive strengths of the book. Along with its unusually wide scope and utilization of the literature, the volume abounds in solid and sometimes quite advanced theoretical analysis in Part I (e.g., an unconventional and useful introduction to monetary systems, pp. 54-59; excellent incorporation of corrective cash-balance effects into adjustment with fixed rates, pp. 54-56, 64-67, 147-48; and elaboration of simple multiplier theory to include the role of money and the export response to domestic income, pp. 76-78) and knowledgeable, lucid, and effective historical surveys and policy interpretations in Part II. And Yeager's conclusions on such matters as "destabilizing" speculation (unlikely with fluctuating rates and well-ordered internal economies; unlikely to be serious with fluctuating rates even with internal disorder; and virtually inevitable and often serious with pegged-but-adjustable rates), the Canadian experience (it does not justify the typical banker and governmental predilection for pegged rates), and the rationality and efficacy of the IMF arrangement (he finds it generally ineffectual and unpromising if not actually appalling) are gratifying to a growing number of us.

The book is written with a solemnity presumably appropriate to international finance.

WILLIAM R. ALLEN

University of California, Los Angeles

Primary Commodities in International Trade, By J. W. F. ROWE. New York: Cambridge University Press, 1965. Pp. xi, 224. \$6.50; paper, \$2.45.

One could be forgiven for assuming, *prima facie*, that Mr. Rowe had followed current fashion in producing a book of statistical tables on international trade. But in actual fact he has not done so; and for this alone we owe him our thanks. What Rowe, in effect, has endeavored to do is to produce a *text-book* on a topic which, as he correctly points out, has had little attention devoted to it recently.

Rowe's definition of what are primary commodities follows from his

definition of primary industries as "those industries which supply foodstuffs and raw materials by agriculture or mining in the form in which they are first exchanged internationally." He limits his discussion of those primary industries and their products by defining his study as being related to *transocean trade*, and not to international trade as we know it. This means, for example, that important regional trade such as intra-European trade is omitted from consideration. Nevertheless we are left with a list of some twenty principal primary commodities which can be regarded as a satisfactory one. The actual list is as follows: Crude Petroleum, Meat, Wheat and Flour, Fats and Oils, Cotton, Coffee, Copper, Wool, Sugar, Rubber, Dairy Products, Tobacco, Rice, Maize, Tea, Cocoa, Tin, Jute and Hard Fibers, Zinc, and Lead. As can be seen, all the old favorites are there!

Briefly, the book is arranged as follows. In Part 1, after clearing away the definitional problems, Rowe presents data on the importance of the 20 given commodities in recent international trade and the main exporters of those commodities. There then follows an excellent, if necessarily sketchy, account of the structure of production in the 20 primary industries. The type of information provided is necessary, I feel, for a full understanding of the position of primary commodities in international trade.

Part II completes the general picture, as it were, since it is concerned with demand and the determination of prices. Following the procedure adopted in Part I, we are given data on the principal markets for primary commodities. Before the important discussion on the pricing process we are given an elementary, and largely unnecessary, account of the "physical process of marketing" the commodities. The chapter on prices, however, makes up for this and it contains a lot of sound common sense. It discusses, mainly, the development and importance of the role played by the "merchant speculator" in establishing and maintaining world prices; as a result there is discussion of the development of future markets. Merchant speculators were given an essentially free hand in determining prices up to 1939 and from about the mid-1950's onwards. In the intervening period the war and its aftermath resulted in large-scale government purchases and sales of primary commodities; so that governments largely determined prices. The appendix to "the determination of prices" chapter attempts to compare the pricing process under the merchant speculator regime with that under government bulk trading. It is not surprising that Rowe reaches no firm conclusions. But most would sympathize with his view that political, social, and other noneconomic motives are likely to govern the determination of price under government bulk-trading schemes; so that less homage is paid to the "equilibrium price" than is likely to be the case under the private enterprise regime.

Part III is historical and largely statistical, being, in effect, a description of the trade in, and the prices of, the primary commodities from 1918 to the present day. This discussion, which at first sight seems unnecessary, is seen, on a rereading, to be extremely valuable in understanding the very important issues raised in Part IV where commodity control schemes are scrutinized.

I regard Part IV, and in particular the chapters on "Control Schemes since 1945" and on "The Mechanics of Commodity Control," as the best part of the

book. This part makes interesting and instructive reading. Furthermore, despite covering some old and familiar ground, it will give stimulation to further theoretical research, especially on the structure of control schemes.

I have an objection, however, to the material in the Appendix to the chapter—which in itself is really excellent—on “The Mechanism of Commodity Control.” My objection is that, despite his statement to the contrary, Rowe has not been rigorous in his treatment of the comparison of the crop-equalization scheme (i.e. producers’ scheme) and the merchant regime. When considering a bumper crop of a commodity and the best theoretical policy for producers to adopt, i.e., whether to introduce their own crop-holding scheme or take what they can get from the merchant speculator, it is possible to make more definite statements than Rowe does by the use of some simple algebra or arithmetic. I am sure the Appendix would gain from a more rigorous presentation of the ideas it now contains. To give one very simple example, if we let: x be the percentage rise in the crop in the bumper year over the “normal” year; m be the merchant’s margin in per cent; Π_B be profit for producers in the bumper year; and Π_0 be their profits in a normal year; it can be shown that (letting x and m be fractions):

$$\text{if } x \leq \left[\frac{1}{1-m} - 1 \right], \quad \pi_B \leq \pi_0.$$

So as a starting point one can say how profit will compare under the merchant regime in a bumper year with that in a normal year, and one can then develop the whole topic from here.

There can be no doubt that with one or two reservations Rowe has produced an admirable book that is well written and, contrary to his own fears about this, well organized. It will serve the needs most certainly of the undergraduate and possibly those of the general reader. Although Rowe has not written a *Principles* as such, a remark once made by Sir John Hicks is well worth recalling: “The ideal which any writer of *Principles* ought to set before himself is that of the classical poet: ‘What oft was thought but ne’er so well expressed.’” Such is the case with Rowe’s book: and it will take a great effort on the part of anyone to achieve success who sets himself the task of improving on this book.

J. L. FORD

University of Manchester.

The Canadian Dollar 1948-1962. By PAUL WONNACOTT. Toronto: University of Toronto Press, 1965. Pp. xviii, 339. \$6.50.

This book consists of two substantially independent parts. Part I was published as *The Canadian Dollar 1948-1958* and was reviewed in this journal (September 1962, 52, 874-75). The present review is restricted to Part II, which discusses the events and policies from 1958 until 1962 when the Canadian government abandoned the system of flexible foreign exchange rates.

Professor Wonnacott chose to concentrate his attention on the economic policies of this second period rather than on the functioning of the mechanism of international adjustment, which was the principal interest of Part I. This choice was made because the mechanism of adjustment continued to function smoothly, and it was the bizarre economic policies of the period that caused the collapse of the system of exchange. High interest rates and a major lengthening of the maturity of the public debt during the depression of the late 1950's were the more painfully inappropriate because the resulting inflow of capital was immediately transferred by the flexible exchange rate mechanism through a current account deficit in the balance of payments. The effect of the budgetary deficit on employment was less with a flexible than it would have been with fixed rate for analogous reasons. The exchange system itself presented real as distinct from imaginary policy problems only in 1961 when the Government interfered directly by announcing their determination that the rate should rise and by purchasing U.S. dollars. They were then met with too much success for their taste. "The least ambiguous lesson of the recent Canadian experience is that a combination of ill-advised and ill-administered policies, occurring at an unhappily inopportune time, is sufficient to create a crisis under a flexible exchange rate system" (page 200).

The study also includes description and commentary on other more specific policies. Policies to reduce foreign control of Canadian industry may have affected the composition and the volume of capital inflows. The complicated scheme to induce the expansion and rationalization of automobile production in Canada by bilateral tariff abolition with the United States and subsidy is admirably analyzed.

Thus, Part II of Wonnacott's book is essentially a brief interpretative history of economic policy in Canada in 1958-62. His arguments are persuasive. This reviewer, for one, shares most of his views. Nevertheless, it must be granted that a priori reasoning plays a very large role in these questions. There are very few data to confirm the analyses. To what extent did the ambivalent xenophobia perceptible in many quarters affect capital flows? Of what significance was the technology accompanying imported capital? Did capital inflows raise the share of labor in national income? These and many other questions need to be answered.

H. C. EASTMAN

University of Toronto

L'économie internationale depuis 1950. By JEAN WEILLER. Paris: Presses Universitaires de France, 1965. Pp. 250. F 18.

This is a puzzling book. It is exceedingly difficult to read. It lacks the lucidity that one is accustomed to expect from French writers. The substance is apparently deep, though evasive.

Professor Weiller belongs to the "Perroux school," the ambition of which is to bypass the "classical" theoretical tradition, by substituting for it a set of new concepts, supposedly more adequate to the real world. The author's anti-classical and institutional bent leads to constant sniping at the orthodox frame

of reference. According to the author, the classical static theories hardly help to explain international economic developments, which result, essentially, from the governments "structural" or "policy preferences."

The book is divided into four parts, dealing respectively with economic policies in Europe and international relations in the fifties, European integration and cooperation, negotiations in the 'sixties between industrialised countries, and international strategies between unequally developed countries.

Starting his analysis from the termination of the Marshall Plan period, the author discusses anew the then fashionable thesis of "structural disequilibrium," and the policies that have led to its disappearance. The nonautomatic and nonorthodox aspects of the policies are constantly being stressed. In the case of the German miracle, the author goes so far as to contend its causal relation with the 1948 monetary reform and the ensuing classical policies. He argues that the rapid and orderly economic growth ought to be imputed partly to the Allies' dirigiste policies before 1948 (1), to aid, and to a favorable industrial structure.

The second part, devoted to "cooperation" and "integration," is mainly concerned with the Common Market, of which the structural aspects and problems are again stressed, as well as the need for joint economic planning. The European Economic Community is said to have originated from a too *laissez-faire* attitude of other international organizations, mainly the OEEC. The Rome Treaty is considered as a compromise between classical free trade principles and the will to "plan." The author's preference for structural planning, of the Monnet type, at an international level remains a basic theme throughout the book.

In the third part, the significance of tariff barriers to international relations is toned down (p. 125). While structural obstacles to the Kennedy-round are mentioned (p. 132), the author maintains that lowering tariffs would not necessarily bring about the most desirable structural shifts in production and trade.

In the chapter on "the role of intergovernmental negotiations in strengthening the international monetary order," Weiller expresses his skepticism towards the restoration of international automatic balancing mechanisms. He would rather rely on the coordination of mutual assistance (p. 160).

The author is most at ease in dealing with the problems of underdeveloped countries. Here, indeed, he can lean on a good deal of recent unorthodox literature. The central problem is that of adapting international specialization to the requirements of domestic planned development. The Heckscher-Ohlin "law" is rejected and flexible discretionary protection to sustain and stimulate planned development is defended. The author pretends that a reasonable rate of growth (5 per cent) would not be possible without selective controls of imports (p. 217).

Weiller's attitude is that of a sociologist. His purpose is to explain the behavior of governments. From an economist's viewpoint, his weakness is to show too much tolerance for irrationality, or to look for some rationality in irrational behavior. He accepts "policy preferences" as given and hardly discriminates between them. As an idealist, he purports to substitute *coopération généralisée* to *laissez passer* as a leading utopia.

This book needs an antidote for French readers, but Rueff's could be too strong.

ROGER DEHEM

*Laval University
Quebec, Canada*

International Finance. By RICHARD WARD. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1965. Pp. vi, 213. \$7.95.

This country's balance-of-payments ills, together with the growing debate on the need for international monetary reform, have generated a great deal of interest in international financial relations among students of business finance and economics. However, very few up-to-date textbooks on the subject are presently available. Professor Ward's comprehensive book thus fills a void and is to be welcomed. It is a largely descriptive and elementary text, written in an easily readable, straightforward style. In the words of the author, "it concerns the international payments mechanism and its economic function." His purpose, Ward states in the preface, is "not to differentiate and mystify the subject, but rather relate it to domestic institutions." In the concluding sentence of the last chapter the reader is warned that the international monetary system described in the book will not be the system operating in the next decade—a prediction not shared by the present reviewer. But, however the system evolves, study of the book will be helpful for a better understanding of the considerations that are likely to dominate the continuing debate on international monetary reform.

The volume begins with a discussion of the measurement of the balance of payments. In preparing this chapter, the author unfortunately could not take advantage of the Bernstein Committee's report, published after completion of the book. The conceptual apparatus used here by the author may not be easily comprehended by the uninitiated student. Explaining the concept of balance-of-payments disequilibrium, he states: "if there is a surplus or a deficit, the country's autonomous outflows are not equal to inflows, and the balance of payments is in disequilibrium." Teachers may feel that this and related observations require more elaborate treatment than provided by Ward. Incidentally, he states in the following paragraph that banks sell their dollar balances to foreign governments (not mentioning central banks), and states that the United States holds its monetary reserve in the form of gold (only subsequently drawing attention to the fact that certain foreign currency holdings of our monetary authorities also serve this purpose). The chapter concludes with a very useful description of the major components of our balance of payments.

In the second chapter, on international investment, Ward defines direct investment abroad rather loosely as "the purchase of capital goods in one country by residents of another country." Monetary capital flows, he says, "become real capital flows through the import surplus which accompanies the inflow of capital." The chapter contains a good explanatory survey of the motivations of U.S. direct investment abroad, discusses portfolio investments, and provides an outline of the major international and U.S. government institutions through which international investment is channeled.

A commendable exposition of the components of short-term capital flows

follows in the third chapter, including a bird's-eye view of the Euro-dollar market. This section is particularly valuable because there are very few such brief surveys available. The present reviewer would take exception to the statement that commercial paper generally carries a maturity of nine months and that exporters sell their accepted bills in the open market through a dealer—except on rare occasions. Nor would he agree with the statement in the following chapter that direct lending is not the most important part of the banks' international role. Also questionable is the author's contention that commercial banking, through its influence on the international system, plays a fundamental role in determining the size of the balance of payments. But this chapter provides an excellent thumbnail sketch of the institutional side of international banking, information not easily come by elsewhere.

In Chapter 5 the author succeeds rather well in clarifying the mysteries of foreign exchange markets and rates. The following chapter, dealing with exchange rates and including brief descriptions of the International Monetary Fund and the Bank for International Settlements, is also very useful. The forward exchange market is treated in a separate chapter, and here again the author has done a praiseworthy job in explaining the many complexities of the subject in a manner that should have considerable appeal to students of finance.

The role of gold in the international payments mechanism is given an appropriate amount of attention, with discussion of both the London gold pool and the various reform proposals aimed at expanding the use of gold in official reserves. Ward makes some generalizations that may not appear acceptable to all teachers of international finance. Thus he suggests that transfers of currency in settlement of international transactions "occur through private capital flows unless the government intervenes in the exchange market"; and he observes that "if a currency other than the dollar is acquired in international transactions, the country acquiring the currency has the right to convert it into dollars." But whether one wants to take exception to such broad statements is largely a matter of personal preference. Again, students will find it most helpful to have in a nutshell a simple exposition of recent reform plans bearing on the role and price of gold.

Two chapters dealing with the interrelationships between the money supply and foreign transactions and between national income and the balance of payments provide a clear and to-the-point explanation of the linkage between the domestic economy and international payments and the channels through which monetary policy affects international financial relations. For the student who wants to be *au courant* on international monetary reform, a concluding chapter on international reserves explains in straightforward language the major proposals made in recent years for improving the international monetary mechanism.

The volume contains useful selected bibliographies at the end of each chapter. Even though this is not a book for the specialist or for the analyst seeking a sophisticated discussion, students can learn a great deal from it about international finance.

FRED H. KLOPSTOCK

Federal Reserve Bank of New York

Foreign Investments in India. By MICHAEL KIDRON. New York: Oxford University Press, 1965. Pp. xvi, 368. \$8.00.

There has been a great deal of discussion in the United States on the desirability of foreign private investment in India. This, however, is the first book that I know that looks into the entire subject in a historical, political, and economic sense—as distinguished from a study of individual cases of foreign private investment.

The author begins with a historical presentation of the role of foreign capital in India under the British empire, the effect of independence upon foreign investment, and the changing character of that investment following independence. He then looks at the changing Indian attitude and policies of the Indian government toward foreign private investment—and the shifts in attitudes and policy under the changing economic and political circumstances, both within India itself and among potential investing countries. This is followed by a discussion of the position of the foreign sector in India today and the reasons for private foreign investment within India and its character. He concludes with an attempt to estimate the benefits and costs of private investment in India.

What comes out most strikingly from this analysis is the bargaining character of the foreign investment process within India. Essentially the author describes a process of the Indian government bargaining with foreign equity investors—large private firms from the United States, the United Kingdom and other countries—or governments, especially from the USSR and East European countries, which are interested in constructing plants or collaborating with the Indian government or private firms. The parties in this bargaining process are the Government of India; Indian private industrial firms which may be collaborating with the large foreign firms; foreign firms which are interested in entering the Indian market for a variety of reasons, only *one* of which may be maximization of profits in the relatively short run; and foreign governments, which may be interested in supporting investment by their nationals or constructing plants within India for a wide variety of political and economic reasons.

The Government of India's interest in encouraging foreign investment is a product of a mixture of motivations: to industrialize in accordance with the Plans; to save its own foreign exchange resources in the process of industrialization; and to gain access to modern technology and eventual freedom from foreign control of this technology. However, the government wishes to gain these without surrendering control of key sectors of the economy or of economic policy to foreign influences. There is also a wide variety of ideological influences at stake, with the government's belief in a "socialistic pattern of society," and the strong nationalist suspicion of foreign investment. Michael Kidron does an excellent analysis of the shifts in government policy and the relatively low importance of ideologic elements in the policy mixture. This is almost a definitive analysis of the pragmatic character of Indian government policy in an important area, in response to circumstances, most notably the recurrent shortages of foreign exchange. It is also clear that the Government of India does not hold a strong bargaining hand in negotiating with potential foreign investing firms, especially in areas of new technology. The government

is interested in comparatively short-term gains and desires them rapidly; the foreign firm is able to forego some of its *potential* short-run gains for longer-term benefits, although the *actual* gains in fact turn out to be high in the short term. One of the very interesting sections of the book shows that, for the large private foreign firms which have invested in India, the economic activities of their Indian subsidiary are only a small portion of their total business; but in the Indian economy these same subsidiaries play a major industrial role.

Private foreign investment has been especially important in "the newer, technologically complex, and patent-protected industries . . . such as the electrical and chemical industries. . . . However, where massive investment is required . . . foreign firms are unlikely to venture more than knowhow. Steel-making, heavy transport equipment . . . for example, have all been left largely to local capital, in these cases through state financing, with foreign firms participating as technical advisers." But while the government's bargaining position is not strong, it is the government that determines into which sectors to permit private foreign firms; which firms to encourage; how many foreign firms to encourage in an industry or a sector; and from which country the foreign collaboration should be selected if there is a choice.

Private foreign firms have done well for themselves financially in India, and if they exercise restraint in terms of the size of the return they expect, and in dealing with Indian government and business, they can continue to do well. They are interested in the longer-term prospects of a potentially very large Indian market, and to get into this market they must do so at an early stage. They are especially interested if they can get in with a relatively small net investment of their own financial capital, as distinguished from technical knowhow, or as distinguished from equipment that can be transferred from other enterprises elsewhere; in that way they can make a rapid recovery of their investment. If they can establish a collaboration agreement with an Indian firm or management group, they will be assisted and protected in their relations with the Indian government, as well as against unfavorable Indian business reaction to the investment. Private Indian firms today generally welcome collaboration as a way of getting foreign exchange and technology; but may oppose it, as they have in the past, if they regard foreign investment as a competitive threat.

Finally, foreign governments have been interested in investing in Indian industry, either by encouraging private investors or themselves constructing plants, as a way of maintaining or increasing their influence within India or expanding sales of their own exports. In the industrial field the Russian and East European countries have made large investments in the public sector, and are apparently willing to invest in the private as well as the public sectors of the economy; British and German firms, with the support of their governments, have built steel plants in the public sector; the U.S. government however has assisted only marginally, if at all, in public-sector manufacturing enterprises, and U.S. private firms have in recent years not invested or collaborated with public-sector enterprises. (This is a self-imposed constraint, on largely ideological grounds, that in my opinion is a mistake. It deprives the United States of impact upon very important sectors of the economy.) The Government of India has used potential Soviet and East European investment

as a bargaining instrument in order to avoid becoming overly dependent on Western investment; where Western firms have been unwilling to invest at terms considered desirable, the government has gone to the Communist countries. (However, Kidron makes it clear that the government has in most cases given the West first option, as for the Bokaro steel plant, or for certain pharmaceutical plants.)

In his conclusions the author asks what India has received from the foreign investment. He raises serious questions whether this investment has in fact provided India with the technological independence that the government desires; and whether India has saved, and will continue to save, foreign exchange as a result of this foreign investment. In both cases he argues that India has not achieved these aims: the technology supplied has been offered on terms that will continue India's dependence on foreign sources of technology, and India has not saved foreign exchange by the investment. These conclusions should be of great interest to Indian officials, as well as to Western officials since they run counter to present policy. However, he does not indicate what the alternatives are for India, given the sources of the technology that India wants and India's relatively poor bargaining position.

I have one main criticism of the book. The author in general seems to believe that India has lost "control" of its industrial sector to foreign investors, and this belief pervades the analysis. However, at times he is embarrassed or doubtful of his own use of the term "control," which he recognizes is very difficult to define, and qualifies it. I would agree with his qualifications and much less with the belief. The Government of India makes the final decisions, and has turned down private investment when the price has been too high, as reportedly in the recent Bechtel fertilizer negotiations; it has successfully put a great deal of pressure on the foreign oil companies for lower prices, and on other foreign companies to expand. While the government has many times modified its policies in order to encourage private investment, whether foreign or domestic, it has, as the author himself points out, controlled the terms of entry and limited the entry into various major sectors, quite apart from the general economic controls after entry. I personally prefer to look at foreign investment in India in the framework of a bargaining analysis, similar to that described earlier, in which the government makes the final decision to accept or reject the investment, in which the various sides have strengths and weaknesses—rather than as one in which either side, the government or the private foreign investors, has or seeks complete control.

This is a very stimulating book. I would consider it a very important book for anyone looking at the Indian economy or at the formation of economic policy within India. I would recommend it also to a broader audience than simply economists or those interested in India. It should be read by U.S. and other Western officials encouraging private investment in India or elsewhere, and by potential private foreign investors, since it presents the best analysis I know of the environment in which they will be functioning. Finally, it should be read by Indian officials dealing with foreign investors, since it takes the first over-all objective look at their efforts, . . . and questions the results.

GEORGE ROSEN

The RAND Corporation

Business Organization; Managerial Economics; Marketing; Accounting

Studies in Mathematical and Managerial Economics. Vol. III, *Management Goals and Accounting for Control*. By YUJI IJIRI. Chicago: Rand McNally & Co.; Amsterdam: North-Holland Publishing Co., 1965. Pp. xvii, 191.

This is Volume III in the series *Studies in Mathematical and Managerial Economics*, edited by Henri Theil. The series applies quantitative methods to the problems of mathematical economics and business management. This book offers analytical (quantitative) approaches to the problems of setting management goals and accounting for control, where the information supplied is based on the intended use of the information. Recognizing the necessity of laying a firm foundation the author develops the basic explanations of the mathematical tools that he desires to use, the approaches to decision-making using these mathematical tools, and then explains how an understanding of the decision process can influence the accounting techniques. The book is of relevance to the theoretical economist interested in the theory of the firm, the managerial economist developing practical approaches to decision-making, as well as the teacher of accounting who wants to study a unique approach to the problems of accounting for control.

Chapter 1 describes the motivation of the book and introduces the mathematics that are used. The mathematical prerequisites are described by the author to be elementary linear algebra and linear programming. This reviewer warns the reader that "elementary" is used in the same sense that a mathematician would use the term. Most readers will find the book to be a challenge.

In Chapter 2 the simple linear breakeven model is explained and then extended to a "piecewise linear" breakeven. Nonlinear functions are thus avoided, but at somewhat of a cost (the cost is noted by the author). The ideas and uses of a generalized inverse (every matrix has a generalized inverse) are used to obtain a solution to "goal programming" problems, a type of linear programming.

Chapter 3 considers complications in the setting of goals (for example, the setting of multiple goals and incompatible goals are reviewed). In Chapter 4 the quantitative feedback (gathering of information) is utilized as a tool for facilitating the goal attainment of the organization. A method of charting the goals of an organization and the feedback generated by the accounting process is developed. Managerial uses of this "goal indicator chart" are discussed.

In Chapter 5 the double-entry bookkeeping system is restructured by establishing a measurement vector for each asset and equity account. Each component of the vector represents a different characteristic of the account. The balance sheet that results not only shows the relevant dollar measures but also various physical units. Chapter 6 is an application of the previous chapters. The basis of the applications is a series of plays of a business game (The Carnegie Tech Management Game). One objective is to illustrate the fact that information useful to management can be supplied by the accounting system that employs the mathematical models developed earlier in the book.

In closing the author states:

The advent of the electronic computer, a mathematics tool, and the development of new mathematics along with numerous management applications in operations research and elsewhere open further prospects for future developments. It is our belief that serious research will show that accounting is neither in conflict with these developments nor isolated from them.

Management Goals and Accounting for Control is an original contribution to the literature of economics and accounting. The process of evaluating and digesting this book will continue for many years. Some books can be readily placed on a value scale, but this reviewer shrinks from passing final judgment at this time on this volume. However, there are several definite statements that can be made. This is an intelligent and sophisticated effort to relate mathematics, economics, and accounting and is worthy of the study of scholars. Anyone working in the broad area of the theory of the firm should read it.

HAROLD BIERMAN, JR.

Cornell University

Industrial Organization; Government and Business; Industry Studies

Economics of Research and Development. Edited by R. A. TYBOUT. Columbus: Ohio State University Press, 1965. Pp. xx, 458. \$7.50.

This latest piece of evidence of burgeoning "research on research" is a collection of essays first presented at a conference in October, 1962. Reflecting the diversity of investigations going on in this area, the papers were variously written by economists, psychologists, sociologists, political scientists, industrial engineers, historians, and even an anthropologist. As usual in collections of this sort, the papers are uneven in quality, and regrettably the overall average leaves much to be desired.

Perhaps the best way to convey the flavor and text of this book is to run down the list of titles of its (seven) Parts, briefly indicating the nature of the contents of each. Part I, the History of Science, contains two papers, one on the role of the state in support of basic science since the seventeenth century, the other an historical review of the increasing specialization of scientific research and the organizational problems of coping with this development. Part II, Industrial Research and Development, contains three papers dealing mainly with the economic determinants of the level, and difference in level, of industrial R and D. A fourth paper, by the anthropologist, is a study of the impact of developments in routine engineering knowledge on productivity change; as a by-product, the paper also reports interesting information on the process of diffusion of new knowledge.

Part III, Internal Organization, has three papers dealing with the organization of research groups. One is an appraisal of the relevance of personality types for the problem of assigning research activities to scientists. The second is an examination of the influence of cooperation on research and quasi-research activities. In the nature of things, it should be of interest chiefly to administrators of research in industry. The third of the papers in Part III is a

study of the process of idea flow and project selection in industrial laboratories.

Three papers also comprise Part IV, on Public Policy and R and D. One is an effort to develop a tool for classifying the social costs and benefits of R and D—in a manner reminiscent of Sir John Clapham's "empty boxes." Then follow two papers dealing with the role of government in the allocation of R and D resources.

Part V, Military Research and Development, contains two economic discussions of R and D problems in the military sector. One is concerned with the proper conduct of R and D projects characterized by great uncertainty with respect to performance, reliability, and cost; as such, its applicability ranges well beyond the military end of R and D. The other is a description of the interrelations between the federal government and contractor firms in the acquisition of new weapons systems.

Part VI, International Collaboration, deals with two experiments in international collaboration in R and D, two papers discussing Euratom and a third the Mutual Weapons Development Program of NATO. Although hard pressed by some others, this group of papers is probably the least edifying in the entire book. Finally, in Part VII, we come to problems of R and D as they relate to the developing economies. One of the more interesting papers of the book is the first of this group, which is concerned with the implications for technology of the resource positions in which today's underdeveloped economies find themselves vis à vis the developed ones. In it, the editor of the book sets forth the thesis that "economic development in the new nations might well result in the long term coexistence of cottage industry and automated process manufacturing, omitting in the middle Western-style skilled labor manufacturing." The other paper is a plea for considerably increased research on social systems. This includes research on peace; on cultural, spiritual, and religious values, and the nature of man; on political power and processes (to relieve suspense, the author of this piece is Kenneth Boulding); and not necessarily least, on the population problem and technology suitable for the resources of underdeveloped areas.

Readers of this *Review* will probably find their professional interest stirred most by the papers in Part II and the first paper of Part VII. Since the contents of Part II fall somewhat within the special competence of this reviewer, let me close this review with a few of the remarks typical of book reviews. The paper by Jesse Markham is another in a series of efforts to link up the conduct of industrial R and D with industry concentration (oligopoly). How long efforts to maintain this Schumpeterian thesis will continue, it is hard to say. But there is mounting statistical evidence against the thesis, and none at all of which I am aware in its favor. In fact, the next paper, by Yale Brozen, reports on a very weak correlation between industry R and D performance and the degree of industry concentration. Although Brozen's data were rather old, his results have since been repeatedly confirmed by recent data.¹ About the only

¹ See D. Hamberg, "Size of Firm, Oligopoly, and Research: The Evidence," *Can. Jour. Econ.*, Feb. 1964; and F. M. Scherer, "Firm Size, Market Structure, Opportunity, and the Output of Patented Inventions," this *Review*, Dec. 1965; and the references in these articles to earlier corroborative studies.

defense left the supporters of Schumpeter in this matter would appear to be the one allegedly erected by Gustav Cassel in the course of an American lecture tour. "What," he was asked, "if the facts don't support your theory?" "Well, then," Cassel exclaimed, "the facts must be wrong." D. HAMBERG
University of Buffalo

The New Deal and the Problem of Monopoly—A Study in Economic Ambivalence. By ELLIS W. HAWLEY. Princeton: Princeton University Press, 1966. Pp. xv, 525. \$10.00.

Professor Hawley has provided a definitive history of national industrial policy in the United States between 1933 and 1939. His footnotes indicate the intensity and wide range of his study. His immediate interpretations are well founded, enlightening, and without bias. His book will become an invaluable secondary source.

He sees the widespread disillusionment with the industrial system in 1933 as generating demands for political action along three different lines (which still persist). One group would have relied on antitrust policy to restore competition (and flexibility of prices), thus achieving a reorganization of the industrial system while at the same time implementing democratic values. Another group favored over-all economic planning, while a third urged government sponsorship of cartels and business planning.

The National Industrial Recovery Act began by giving some comfort to each of these groups. But in administration it developed almost a sustained stalemate, and by the time it was struck down by the Supreme Court it had few friends. In fact its main achievement was to fortify private monopolistic arrangements for a time. In its wake came a policy of government sponsorships of cartels, restricted, however, to a few industries (petroleum, coal, and transportation) and to the distribution trades. Each of these was in a position to conceal its drive for profitable restrictions by reference to the conservation of natural resources, national defense, protection of the small man, and the like. But over-all government planning was no longer politically feasible. Following the depression of 1947 antitrust policy was reinvigorated under Thurman Arnold, but its implementation was cumbersome, and it was not uniformly applicable. Consequently it failed as an anticyclical weapon or as a means to economic expansion and faded away in the nationalistic glare of approaching war. In the end the policy of the Roosevelt administration was one of counterorganization, or creating monopoly power in areas previously unorganized (labor, agriculture).

The change from time to time in the relative weight of each of the three views on government policy always left some room for each of them. Policy throughout the period was, therefore, a bundle of inconsistencies. These changes were due in part to changes in economic conditions. Depression revived the argument about rigid prices and gave renewed vigor to pressure for more active antitrust policy. But it also enlivened arguments for planning. Such planning as occurred was partial and, as indicated above, under shelter of special circumstances.

The persistent pursuit of policies made up mutually conflicting elements calls for explanation. Hawley blames a popular demand, on the one hand, to

be allowed to continue to enjoy the material goods and services provided by an industrial order with a high degree of collective organization and, on the other hand for the maintenance of a system as free as possible from centralized control and adjusting itself automatically to market forces while at the same time preserving human dignity. But the survival of this ambivalence itself requires explanation.

The period of Hawley's study is too short to help greatly in explaining this survival. He doubts, however, that the experience of the thirties will reduce confusion in future policy even though economic conditions have changed. Monopoly and rigid prices are no longer regarded as major causes of depressions. Inflation, labor power, and the wage-price spiral are of more concern, but point toward monetary and fiscal policy. Nevertheless the economic power of monopoly is still feared and its contribution to the waste of resources and inequality of incomes criticized. Even so, current policy, like that of the New Deal years, is still a maze of conflicting cross currents. In this respect there is, seemingly, no trend. Future policy is expected to "remain confused and contradictory . . . programs designed to combat monopoly will still be intermingled with those designed to promote it." This conclusion looks less bold, however, in view of the exclusion of "revolution, or drastic changes in techniques, attitudes, values and institutions." In fact it almost comes to saying that in the absence of the major influences making for change there will be no change.

The pessimistic conclusion that confusion and ambivalence are likely to continue presumably rests partly on Hawley's view that the experience of the thirties, if relevant, suggests "the limits of logical analysis and the pitfalls inherent in broad theoretical approaches" as well as the necessity for making due allowance for the intellectual heritage, current trends of opinion, and the realities of pressure group politics. It is unfortunately true that economic analysis has largely failed to specify the causes of industrial concentration or to measure its consequences in terms of either the efficiency of the use of resources or the distribution of incomes. Elaboration of the monopoly concept into a family of imperfections or kinds of monopolistic competition has not helped. If economists had been more successful, perhaps some of the arguments of the three pressure groups upon which Hawley's analysis is based might have been undermined. But, as he indicates, the intellectual heritage, current trends of opinion, and like factors also contribute to the formation of public policy. Although economic analysis might reduce their influence, it cannot eliminate it. But in this respect does social policy regarding the industrial system differ greatly from social policy in many other socioeconomic fields? Problems become a matter of political concern precisely when the need for compromise among objectives becomes a pressing need.

Everyone interested in industrial organization and control needs Hawley's work and will enjoy his lucid presentation of a complex problem.

Inter-Economy Comparisons: A Case Study—A Comparative Study of Industrial Development, Currency Devaluation, and Inflation. By LEONARD A. DOYLE. Berkeley and Los Angeles: University of California Press, 1965. Pp. xiii, 232. \$6.00

Even the full title of this volume does not suggest its contents. It is not concerned with intercountry comparisons of national product, industrial structure, prices, or exchange rates. Rather, the study aims at comparing the capital and operating costs of two cement plants, one the cement plant of the Indonesian Government at Gresik in East Java and the other the Cushenberry plant of the Permanente Cement Corporation in Southern California. Yet the title is not altogether misleading since the comparisons do involve some consideration of the effects of inflation and exchange rate variation; presumably the attempt to determine the contribution of the Gresik plant to the economy of Indonesia justifies the reference to "industrial development."

There has been much speculation and little systematic enquiry regarding the ability of the less developed countries to absorb modern technology. This study focuses on two large plants of similar design and vintage (both came into operation in 1957) in order to explore some of the issues, especially those involved in making cost comparisons. But while developments in Indonesia towards the end of the 1950's were such as to enliven the investigation, Professor Doyle's painstaking cost-accounting approach has to hurdle three difficult obstacles, viz. rapid price inflation, government ownership, and a complex and unstable exchange rate situation. A plant in some more placid setting would have reduced the number of variables and greatly simplified the task of arriving at meaningful conclusions.

The greater part of the book (five chapters out of eight) consists of a discussion of the principles underlying the author's detailed computations of investment and operating costs, with special attention devoted to such subjects as the measurement of depreciation and of interest charges in a socialist economy suffering from rapid inflation. Ordinary business accounting concepts are adapted to the special circumstances surrounding the comparisons, and much space is devoted to justifying these departures from conventional practice.

Despite Doyle's careful examination and application of accounting precepts, the reader who is interested in what he can learn from the figures will often be at a loss, the more so as the author fails to summarize and interpret his findings. While the costs of the Gresik plant incurred in rupiahs are perfectly definite in that currency, the rupiah value of imports depends of course on the exchange rate used. Not only did the rate change; at no time did the official rate, which Doyle generally uses, come very close to measuring the real purchasing power of the rupiah vis-à-vis the dollar. In these circumstances not only the U.S.-Indonesian comparisons of capital and operating costs are indefinite, but even comparisons of relative costs are affected by the rate because of imports. This reviewer found it difficult to know what to make of many of the calculations. Or, for that matter, of such statements as: "Whatever one's views of the theoretical procedure necessary to compare investment in a country with an overvalued currency, the practical solution must be to accept the official rate for statistical purposes."

To the extent that the author provides comparable information in physical units, the results are of greater interest. We learn, for instance, that the Gresik plant employed almost 5 times as many workers (and paid them only 6 per cent as much, at the official rate); yet Cushenberry's output was over one-and-a-half times as high. Moreover, investment in the Gresik plant, no matter how measured, substantially exceeded the cost of the Cushenberry installation. The reasons behind these differences are interesting. The Indonesian firm had to provide housing, a school, a fleet of buses, recreational facilities, etc. for its workers; and electric power, docking, oil storage and rail facilities, and even a paper bag factory for its operations. The warehouse had to be larger than in the United States so that an adequate supply of spare parts could always be kept on hand, and the machine shop also had to be more elaborate to make or repair equipment which in the United States could be made or serviced by outside firms. Clearly, a very much greater input of capital and labor is required to produce cement in a country still lacking the social and other overhead capital which in industrialized countries is taken for granted and shared broadly. The larger Gresik labor force was in part also attributable to special factors: the Gresik plant is a state enterprise, unemployment is widespread, the wage level is low in relation to the value of the product, the wage spread is narrow for workers at different levels, etc.

Doyle tries to assess the importance of the Gresik plant to the Indonesian economy, and concludes that for all practical purposes the net benefit is the saving in foreign exchange on cement imports ("the real costs represented by managerial and operating personnel and by domestic materials and supplies can be regarded as zero"). In 1959 the foreign exchange saving amounted to around \$4 million. In the same year the marginal contribution to Indonesia's foreign exchange position of a ton of cement was at least \$16, after allowing for all dollar costs, including depreciation on a replacement basis of the dollar portion of the investment. In the circumstances, as he points out, a policy of keeping the plant short of the foreign exchange needed for expansion and efficient operation would be shortsighted.

Doyle has some provocative points to make, of which the following is an example:

In selecting industrial projects in a developing economy it may be desirable to favor those for which the ratio of local currency to foreign exchange is relatively low. In spite of the rather general belief that newly independent nations require enormous sums of foreign exchange for capital investment, the fact is that the chief limitation on industrial capital formation is often local currency rather than foreign exchange. This is particularly true of countries, such as Indonesia, that elect state enterprises rather than private foreign investment (p. 31).

Neither this argument nor a number of the others are developed as fully as they might be, however, and supporting references to the literature are almost entirely lacking.

In a book that attempts to cover engineering, accounting, and economic considerations, careful organization is especially important. Many readers will

justifiably feel that the author could well have given more thought to the arrangement of his material.

WILLIAM I. ABRAHAM

New York University

The Economics of Regulation—Theory and Practice in the Transportation and Public Utility Industries. By CHARLES F. PHILLIPS, JR. Homewood, Ill.: Richard D. Irwin, 1965. Pp. xvi, 783. \$10.00, college price.

One advantage of a dilatory review of a book which has already become a standard text is that it may serve to convert the heathen. To this end, let us first appreciate a passage which is typical of most of the book:

In general, commissions have acted only in response to complaints or when a company has filed for a rate increase. Few investigations have been started on their own initiative. . . . Most of the commissions have been compelled to devote their time to the determination of the rate level, leaving little time to spend in investigating the rate structure. But even when the rate level has changed, the commissions have tended to approve across-the-board increases, thereby permitting all rates in the structure to move together and preserving the existing pattern of differentials. . . . (p. 389).

This passage is not quoted because it is especially wise or especially felicitous, but because it is representative. It projects truth and common sense. Anyone familiar with the field of public utility regulation would agree with most of it. Most would agree with all of it. But, aside from Emery Troxel, not many economists have thought to spell out the point so carefully.

In addition, Charles Phillips is conspicuous for his homework even in a field which abounds in homework. The sources are here in abundance: old and new, theoretical and institutional. After endless exposure to *Interstate Commerce Comm. v. Alabama Midland Ry. Co.*, 168 U.S. 144 (1897), I was still pleased to meet someone who had obviously gone all the way back to the decision, and who could summarize the special frame of reference so crisply:

. . . when evidence was presented to the Court, it was shown that the river—the water competition shown in the evidence before the ICC—was dry half of the year, that it was but three feet deep, and that the presence of overhanging trees made the use of boats impossible (p. 111).

But, like all homework, this takes time. And the opportunity cost can be considerable. For example, if there is one question upon which economists have been agreed almost since the profession began, it is the economics of the back haul. If there is also one issue on which the Interstate Commerce Commission has covered itself with shame, it is this same issue of the back haul. Phillips quotes one of the least worthy of the Interstate Commerce Commission's exercises, as reported at 4 MCC 189 (1938):

. . . the traffic of one truck operator may preponderate in one direction, whereas that of a competing operator may preponderate in the other. As between operators, therefore, the application of the "out-of-pocket" cost method of making rates might well result in a break-down of the rate structure in both directions.

This is a perfect example of the kind of economic hobgoblin with which the Interstate Commerce Commission cannot contend, for the excellent reason that it exists only at Twelfth Street and Constitution Avenue. But Phillips refuses to exorcise it. Instead he comments:

Compared with the railroads, therefore, where an unbalanced movement of traffic in one direction is frequently encountered by all carriers, a particular motor carrier may have a back-haul problem in one direction, while another carrier faces a similar situation in the opposite direction. To allow both motor carriers to reduce their back-haul rates to out-of-pocket costs would not be justified . . . (p. 381).

Generalizing from the Interstate Commerce Commission and from Phillips, one would have to conclude that load factor has nothing to do with costs, that unemployment of factors should be protected against employment, and that a principal object of regulation is to produce waste in the place of efficiency. This perversity appears only rarely in Phillips—much less rarely than in Interstate Commerce Commission decisions—but in an economic text it should not appear at all.

Which brings us to the central question: what books have a comparative advantage in which markets?

1. Phillips should be in every reputable library. The style is intelligible to all and condescends to none. The factual statements are remarkably accurate. The research and scholarship embodied in the book are formidable.

2. When considering Phillips as a text, the first question must be: why is a government regulation course in the curriculum? If this can be answered, the second question might be: can any one book be both theoretical enough, and factual enough, to carry the entire load in such a course? If the response to this is negative, as I suspect it must be, the question is: does Phillips earn high marks on the factual material? The answer to this is a most emphatic "yes."

3. Finally, then who does carry the load of theory? Perhaps some economists would modestly nominate themselves, in their classrooms, for this honor. But if they seriously believe that they can convey economic theory by their own unaided lectures, they probably have not been reading their examinations very carefully. And, for all its virtues as a compendium and as a careful, scholarly, and dispassionate summary of how things really are, the Phillips book will require them to lengthen their reach to pull its institutional material closer to standard analysis.

The trouble with microeconomics is that it is so cluttered with facts. This is the nature of the beast. No amount of free-lance theorizing can alter it. *The Economics of Regulation* should be praised for adding to the pre-existing stockpile of facts. But it cannot be praised for pursuing a sometimes uneasy course between economics and other disciplines.

The Phillips book already occupies a secure niche in economics, as indeed it should. But its educational value would be greater, and its niche more secure, with more rigorous economic and financial analysis.

JAMES R. NELSON

Labor Economics

Hoffa and the Teamsters—A Study of Union Power. By RALPH JAMES AND ESTELLE JAMES. Princeton: D. Van Nostrand Co., 1965. Pp. xviii, 430. \$6.95.

The ease with which David Beck, former president of the Teamsters' Union, was toppled from power under the onslaught of the McClellan Committee led many a superficial observer of the labor movement to assume that James Hoffa would follow the path of his predecessor when McClellan's sleuths turned their attention to him. Yet, paradoxically, Hoffa's power within his organization seemed to thrive and increase under the repeated onslaughts of the Committee and the former Attorney General of the United States, Robert Kennedy. The expulsion of the teamsters from the house of labor, seemed to have little impact on the teamsters' fortunes under Hoffa's leadership. They continued to gain both in membership and economic improvements for their constituents.

This seeming paradox is studied in depth by Ralph and Estelle James. They have given us a penetrating story of a man, an institution, and its impact on the larger society within which both leader and organization function. The writers were granted a unique opportunity by Hoffa himself to spend some 90 days as part of his entourage observing him in action at close quarters. Ralph James was introduced as an egghead member of the staff at all private conferences. The resulting account of their observation is a tribute to their scholarship and integrity, and incidentally a treatise on how to do scholarly research without being seduced by a sponsor. This is no small achievement for the social scientist who is confronted by the problem of keeping his channels of inquiry open despite the knowledge by the sponsor that the findings reported may be something less adulatory than the typical institutional *Festschrift*.

The Jameses have avoided two traps—the temptation to yield to the sensational journalese of the inside dopester on the one hand, and on the other to reduce the colorful actors in a richly human drama to the role of abstract beings in the grip of abstract forces.

What emerges is the following: (1) a psychological study in depth of the complex personality of James Hoffa; (2) a dynamic study of the nature of negotiation and administration of collective agreements by an intuitive expert; (3) a first-rate economic analysis of the impact of the Teamsters' Union upon the fortunes of its constituents and the economy at large.

A much more complex personality emerges from the pages of the James's book than the simple-minded thug portrayed in the newspapers at the time of the McClellan hearings. Hoffa emerges, ruthless to be sure, but nevertheless sincerely concerned about the welfare of his men. Endowed with a brilliant mind, but one not given to abstraction, he is a master craftsman, drawing upon the contents of a file-cabinet brain in which are compartmentalized the immeasurably complex details of all teamster agreements.

What makes Jimmy tick? The Jameses express their complex frustration in attempting to understand him. He is a man who brooks no opposition in carrying out policy, yet maintains on his payroll outspoken oppositionists to his policies. He is a complete puritan in his personal habits, eschewing smoking,

drinking, and sexual escapades, yet tolerating around himself men whose incompetence is exceeded only by their bawdy lechery.

Completely contemptuous of labor history, he is the labor counterpart of the Senior Henry Ford to whom history was bunk. Yet he is utterly captivated by Farrel Dobbs, the intellectual Trotskyite, whom he acknowledges as his mentor in changing him from a young punk to a superstrategist with a new concept of the strength of the teamsters' organization.

Hoffa has built upon the strategic organizational concepts laid down by Farrel Dobbs. It was Dobbs, with the aid of the Dunne brothers, who understood the strategic importance of the over-the-road truck driver in making the Teamsters the keystone of the Twin Cities' labor movement, to whom all other unions looked for aid.

The Jameses give a detailed picture of the way Hoffa has used this strategic concept to convert a collection of independent local baronies held tenuously together by per capita payments to old Dan Tobin, former national president, into a nationally integrated organization with national agreements. They credit Hoffa with mastery of the intricately detailed economies of the trucking industry. The Jameses indicate that, through collective bargaining, Hoffa has been able to do more for his members than other leaders of more respectable stamp, but possessing less strategic power.

The authors indicate that Hoffa's manipulation of the pension funds may entail a future cost when many members will blame future administrators for not paying the pension which the members think they have gained. On the other hand, they reject the moral evaluation of Hoffa by Senator McClellan as the labor movement's worst enemy.

Hoffa does emerge as a power-loving despot, but then what leader of an organization doesn't love power for power's sake? The Jameses are inclined to believe that Hoffa's reputation stems more from the early days of Detroit's violence in which he gave as good as he got.

What makes the James's study so refreshing is the manner in which their problem dominated their techniques. This study is an academic revival of the John R. Commons' institutional tradition in which scholars were dominated by the interest evoked by their problem rather than the status stemming from a pyrotechnical display of powerful tools subjected to trivial problems.

Their work is an indispensable tool for the student of labor or transportation.

WILLIAM GOMBERG

University of Pennsylvania

Labor Migration and Economic Growth—A Case Study of Puerto Rico. By STANLEY L. FRIEDLANDER. Cambridge, Mass.: The M.I.T. Press, 1965. Pp. ix, 181. \$6.00.

This book is based on the author's doctoral dissertation. Its subject is the extent to which migration from Puerto Rico to the United States has aided the economic development of the island's economy, and its goal is to demonstrate that large-scale emigration from Puerto Rico to the United States was crucial in raising per capita incomes in Puerto Rico and in supporting the rapid rate of economic growth the island has experienced since 1945. Chapter 1 is intro-

ductory, and in Chapter 2 the author presents a theoretical analysis of the effects of emigration on economic development. The remaining five chapters deal specifically with the Puerto Rican experience; the last chapter summarizes the study and suggests applications of the Puerto Rican experience to the problems of other underdeveloped areas.

Chapter 2 occupies 32 pages, and I feel it should have been shortened by about 90 per cent. The author admittedly derives much of the analysis from an article by R. R. Nelson in this *Review* (December, 1956). The essential points are that in overpopulated areas population growth responds very rapidly to economic development because both fertility and (especially) mortality respond (positively and negatively, respectively) to rising income levels. Thus since increases in national income are not matched by increases in per capita income, but possibly by decreases, either substantial investment of foreign capital and/or large-scale emigration are necessary to promote increases in per capita income and, consequently, saving, which eventually steer the developing economy toward self-sustained economic growth.

Not only has the logical framework of Chapter 2 been worked out elsewhere, but the terminology and symbolism used by the author seem to confuse, rather than to clarify, the theory. For instance, in equations (2.1) through (2.3) on page 13, the author states:

$$(2.1) \quad Y = f(K)$$

and

$$(2.2) \quad S = \Delta K \quad (\text{by definition}),$$

where K is the capital stock, S is saving, and Y is national income. He then substitutes (2.2) into (2.1), obtaining

$$(2.3) \quad Y = f(S).$$

But if (2.3) is true, it does not seem to follow from (2.1) and (2.2). Subsequently it is stated that "the rate of growth of output is a function of the change in capital formation . . ." and

$$(2.5) \quad d(Y/Y) = h(d(S/P)) \text{ sic!}$$

where S/P is per capita saving. Much of the remainder of Chapter 2 is equally confusing.

In Chapter 3, the author discusses emigration and population growth in Puerto Rico; there is a summary of economic and demographic conditions as of 1940, and aspects of demographic changes and migration since then. Between 1945 and 1962, nearly 600,000 Puerto Ricans emigrated to the United States; this constituted 85 per cent of the total emigration during the twentieth century. That this was a substantial number of people can be seen by comparing the figure with the 1960 population of Puerto Rico—2,349,544. The author emphasizes that the figures probably understate the importance of migration to the population growth of the island, since emigrants tended to be in the most fertile age groups and would have produced many children who, as it turned out, were born on the mainland. (Emigrants in the 14-34 age groups

numbered 346,107, compared with a population of 681,434 in the age group on the island in 1960.)

Subsequently (p. 57) the author discusses his calculation of the amount of Puerto Rican emigration from 1940 through 1960. The estimate—577,994—is based on a comparison of the “expected” population (derived from base-year population, birth, and death rates) with the “actual” population over the period observed. He compares his estimate with “migration statistics” and notes almost perfect correspondence; but the author does not state the source of the “migration statistics,” and one suspects they were based on the same sort of estimates as the author’s, especially since data from other sources (probably annual estimates of net departures) presented in Appendix A suggest that migration over the same period amounted to 600,500. While the discrepancy is not large, the author’s vagueness in describing the accuracy and sources of his data is annoying and unnecessary.

In Chapters 4 and 5 the author discusses the causes and effects of the skill mix of the migration stream. The principal hypothesis tested is “that the occupational earnings differentials would stimulate the movement of a larger proportion of unskilled to skilled laborers than the existing ratio in the economy after a minimum income per capita is attained” (p. 75).

The author notes that the labor force in Puerto Rico grew slowly, or shrank, during the period of high postwar emigration (depending upon which dates are compared). This would seem to be caused mainly by the typically high labor force participation rate in the age groups constituting the bulk of the migration stream. The author sets himself the task of showing that despite the high labor force participation of the emigrants, migration caused Puerto Rican per capita income to *increase* because the quality of the labor force was improved. The author relies on two sources of data to estimate the impact of the migration on the skill mix of the Puerto Rican labor force. One is a comparison of the 1950 and 1960 occupational distribution of Puerto Ricans in the United States with the occupational distribution in Puerto Rico. He correctly recognizes that the occupation titles of jobs held by Puerto Ricans in the United States may well be different than those that would have been held by the migrants if they resided in Puerto Rico; he further suggests that the occupational mix of the migrants in the United States is more highly skilled than it would have been in Puerto Rico. I am inclined to agree. The comparisons imply that the migrant group in the United States contains a much higher proportion of operatives and service workers, other than domestic, and the same or lower proportions of other occupations (including professional and technical; farmers and farm managers; owners, managers, and officials; clerical and sales; craftsmen and foremen; domestic service; and laborers) than does the labor force of Puerto Rico. Thus, if the migrants were removed to Puerto Rico and placed in their United States occupational categories, the proportions of these other occupations in Puerto Rico would be unchanged or reduced. Whether this suggests, as the author asserts, that the migration improved the skill mix of the Puerto Rican labor force, seems unclear to me. On the basis of the 1950 and 1960 censuses, it seems more likely

that migration increased the proportions of workers at both extremes of the occupational distribution in Puerto Rico.

Data from airport surveys conducted since 1957, however, suggest that perhaps half of the experienced workers in the migration stream were from agriculture. The author uses these data to support his hypothesis that migrants substantially upgraded their occupational status upon emigrating to the United States, and that the average occupational and skill level of Puerto Ricans emigrated has been lower than the average of those who remained. However, this leaves the author in the difficult position of having to reconcile his conclusions about the skill mix with data showing that in both 1950 and 1960, in practically all age groups, the educational level of migrants was higher than the average educational level of the population of Puerto Rico. He rationalizes the apparent contradiction by asserting that "the educational level of the migrants is not significantly higher than the remaining population in terms of qualifying for more advanced occupations," and that "the migrants may have a higher education than the people in Puerto Rico but a lower education than the people in the United States" (pp. 102-3). I find both of these arguments unconvincing. It is the effect of emigration on the average quality of the Puerto Rican labor force that is the issue; it appears that no matter which way one views the educational data, the emigrant Puerto Ricans had no less formal education than those who did not emigrate.

Perhaps one source of the apparent contradiction between the occupational mix and educational mix of the migrants is found in data reported in Chapter 5. Information in the airports' surveys of Puerto Rican emigrants suggest that, in all years from 1957 through 1961, slightly over one-half of the passengers interviewed were not in the labor force. (This group included students.) It is possible that one of the causes of migration was the difficulty of relatively able and well-trained persons in Puerto Rico to obtain employment in relatively skilled jobs at home. Thus, persons who were not in the labor force in Puerto Rico, or who were forced by lack of job opportunities to take low-paying, unskilled jobs, found opportunities for the employment of their talents more favorable in the United States. A possible source of such interregional differences in the ease of entry into the types of jobs the migrants have found on the mainland may be the relatively very high minimum wage rates imposed in Puerto Rico. Minimum wages in Puerto Rico and some of their effects on the growth of employment opportunities have been discussed by Lloyd Reynolds in the March, 1965 issue of this *Review*.

In Chapter 5, the author discusses the causes of the skill mix of the migration stream and cites evidence that the principal cause was "[differences] in the sizes of the absolute [earnings] differentials (in percentage terms) among occupations" (p. 119). Unfortunately, the author is not able to compare directly the alternative wages of migrants in Puerto Rico and in the United States, as data are available only on earnings in occupational categories; they are not classified by the national origin of the workers employed in them. Thus, comparisons are not made between identical occupations in Puerto Rico and the United States, but between occupations which the author feels Puerto

Rican migrants have been most likely to leave in Puerto Rico and to enter in the United States.

Earnings of farm workers in Puerto Rico are compared with earnings of custodians in New York, and so on. In 1952, the earliest year in which comparisons between weekly earnings are made, the differences ranged from a low of \$30.45 between office workers in the United States and clerical and sales workers in Puerto Rico and a high of \$51.10 between craftsmen in the two areas. In 1962, the same occupations also displayed the lowest and highest differences—\$45.82 and \$76.60, respectively. The author theorizes that the reason farm workers constitute the largest single occupational group in the migration stream despite the fact that their earnings gain (the difference between median weekly earnings of custodial workers in the United States and farm workers in Puerto Rico was \$72.60 in 1962) would appear to be somewhat less than that of craftsmen, is that their *relative* gain (the proportionate increase over their Puerto Rican alternatives) is greatest. I find this rationalization unpersuasive, both because the differences in earnings gains do not seem large enough to explain the occupational mix of the migration and also because equally plausible alternative hypotheses are either rejected almost out of hand or not even considered.

The author finds that "The migrants did not respond to the general rate of unemployment for all Puerto Ricans in the United States, nor did they respond to unemployment rates by occupations as they did to earnings differentials by occupation." His evidence is based mainly on a comparison of the differences in aggregate and occupational unemployment rates between Puerto Rico and the United States for 1960 and 1950. It is true that for most occupations, but not in the aggregate, the unemployment rate, as reported in the United States *Decennial Census of Population*, was higher in the United States than in Puerto Rico. This was true even for operatives, who constitute about half the Puerto Rican labor force in the United States. Unfortunately, it is dangerous to infer much from a comparison of decennial census unemployment rates, as it is widely recognized that the number of marginal workers was typically underreported; the underreporting seems to have been very great in Puerto Rico, where the census unemployment figure for 1950 was just over 5 per cent while the Puerto Rico Bureau of Labor Statistics reported a rate of 14.2 per cent for men and 11.8 per cent for women. The Puerto Rican official statistics are thought to be more reliable than those collected by the Census Bureau. (See, for instance, A. J. Jaffe, *People, Jobs, and Economic Development*, Glencoe, Ill., 1959, pp. 275-76.) I have not examined the 1960 data for accuracy, but I suspect that, while reporting in the decennial census has improved, important errors still remain.

An alternative hypothesis not considered by the author is noted above; high minimum wage rates may have restricted the entrance of relatively well-trained but inexperienced workers from entering the more skilled occupations. (On this point, see also M. W. Reder, "Wage Structure and Structural Unemployment," *Rev. Econ. Studies*, 1964, 31 (4), p. 316n.). It is also likely that the occupational mix of the migration is partly a function of the age of the migrants. Persons most likely to move *cet par.*) tend to move while they are

young. Thus, the more highly skilled members of the Puerto Rican labor force may well be those who, for personal reasons, have elected not to emigrate. (See, for instance, Gary S. Becker, *Human Capital*, New York, 1964, pp. 50-51.) Even in the short run, the young have fewer commitments, economically, sociologically, and psychologically, than the old.

Chapter 6 contains an analysis of the effects of labor quality on the growth of output and productivity. The author states that "falling average productivity implies falling marginal productivity of capital. Apparently investment in Puerto Rico has not decreased in response to the declining marginal productivity of capital. . . . In any event rising real wages did not seem to retard investment on the island." Not only is the argument marred by the logic involved in the average-marginal statement, but no convincing empirical evidence is presented to support the author's assertion regarding the effect of rising wages on investment. Finally, the author moves from his assertion that emigration, by improving the quality mix of the Puerto Rican labor force, raised income per capita, to the conclusion that "emigration, therefore, played an important indirect role in stimulating capital formation by allowing gains in output to be translated into gains in income per capita, which stimulated savings per capita throughout the economy" (p. 140). This appears to be an important part of the analysis of Puerto Rican emigration, since if this process were to occur elsewhere, it would, in the terminology of the book, assist underdeveloped countries to achieve self-sustained economic growth. Unfortunately, the author fails to note that net foreign investment (mostly by the United States) in Puerto Rico appears to account for a substantial proportion of capital formation on the island. According to the *Statistical Yearbook of Puerto Rico*, net foreign investment amounted to more than 85 per cent of the level of gross domestic investment from fiscal 1957 through fiscal 1961. (I am indebted to my colleague, Walther Michael, for discussion of this point.)

The chapter concludes with some estimates of production functions for the Puerto Rican economy in an attempt to estimate the influence of education and improved labor force quality on Puerto Rican economic growth.

While this book deals with an important subject, I cannot recommend it as required reading for those wishing to learn something about the role of emigration in aiding overpopulated and underdeveloped countries to achieve self-sustained economic growth. It is clear that Puerto Rico's nearly unique connection with the United States has overwhelmed most evidence that can be gained regarding the influence of emigration on domestically financed capital formation. It does seem plausible that, given the rate of capital formation in Puerto Rico, emigration raised the productivity and the wages of both emigrants and those remaining on the island. Moreover, it does not seem implausible that if emigration had been smaller and perhaps, minimum wage rates less rigorously applied, capital formation would have been still greater than the large amounts that were in fact achieved.

Fringe Benefits: Wages or Social Obligation? An Analysis with Historical Perspectives from Paid Vacations. By DONNA ALLEN. Ithaca, N.Y.: Cornell University, New York State School of Industrial and Labor Relations, 1964. Pp. ix, 273. \$4.75; paper, \$2.50.

This book is an analysis of the development of fringe benefits for wage workers in U.S. industry. Miss Allen illustrates her analysis with the history of one type of fringe benefit: annual vacations.

Miss Allen's thesis is that many (though not all) fringe benefits have undergone an evolution similar to that of vacations. In the first phase, management accepts a "social obligation," such as providing an annual rest period for its employees. The second, or union, phase has three stages: first, the unions insist that the company include this fringe benefit in the contract; second, they proceed to liberalize it; third, they work to eliminate the management qualifications and restrictions upon the right to the social benefits. From this it is but a short step to the position that the fringe benefit is in fact a form of deferred wages. In this interpretation, vacation pay is money earned by the worker during his period of employment, and put aside for him by the employer.

Miss Allen believes that this trend has most unfortunate consequences. In the first place, the "deferred wages" doctrine has enabled employer-dominated state unemployment compensation boards to deprive employees of their unemployment benefits while receiving vacation pay, severance pay or similar benefits. She feels that if the deferred-wages doctrine were taken to mean that these benefits were simply funds owed by the company, then the worker would *not* be deprived of his unemployment benefits. However, she feels that this doctrine permits a biased interpretation—that the money is owed specifically for time not worked.

Her second, more fundamental, objection to the deferred wage doctrine is that, when we regard payments into vacation, pension, or unemployment funds as part of the employee's wage, we remove the company's social obligation to provide for its employees.

Miss Allen views the postwar period as one in which the political climate has been unfavorable to the labor movement's efforts to secure social legislation, but in which the economic situation has favored the more powerful trade unions in their struggle to wrest these social benefits directly from employers. Thus, it seems unfortunate to her that the unions have been undermining the view that employers have a social obligation to their workers by insisting that not only does the worker have a right to these fringe benefits, but that these benefits are in fact a form of wages for services rendered.

However, it is not necessary to share Miss Allen's sympathetic view of corporate paternalism in order to appreciate this book. The history of the annual holiday in the United States from 1900-1960 is presented at length. Not only are the quantitative gains in the spread of vacations chronicled in some detail, but a very interesting analysis is given of the changing employer and employee attitudes towards this custom.

KLEIN, S. The road divides—economic aspects of the Sino-Soviet dispute. Hong Kong: Internat. Studies Group, 1966. Pp. ix, 178. \$7.50.

The author discusses the Soviet Union's aid to and trade with China during the 1950's, the reasons for the "break" in 1960, and its economic consequences for China. He attributes an unusually large part of China's development to Soviet aid, reviews a long history of Sino-Soviet conflict and expects the current estrangement to continue and even intensify, and thinks that China is still in the "Great Slide Backward." Numerous photographs and typographical errors.

MELNYK, Z. L. Soviet capital formation: Ukraine, 1928/29-1932. Munich: Ukrainian Free Univ. Press, 1965. Pp. xxvi, 182.

This book is "one of the first Western studies in the field of regional economics of the Soviet Union." The author finds that "in the course of the first Five-year plan period (1928/29-1932), five billion rubles in capital funds (\$4.34 billion, at the current official rate of exchange), or almost thirty per cent of total revenue collected by the central USSR government in Ukraine, were withdrawn from Ukraine and spent elsewhere in the Soviet Union."

NOTES

SEVENTY-NINTH ANNUAL MEETING OF THE AMERICAN ECONOMIC ASSOCIATION

Hilton Hotel, San Francisco, California—December 27-29, 1966

Preliminary Announcement of the Program

Tuesday, December 27, 1966

8:30 A.M. ECONOMIC ANALYSIS OF WATER RESOURCE PROBLEMS (Joint Session with the American Farm Economic Association)

Chairman: MAURICE M. KELSO, University of Arizona

Papers: Nonmarket Values and Efficiency of Public Investments in Water Resources

A. ALLAN SCHMID, Michigan State University

Urban Water Supply Economics: A Second Look at New York City and Southern California

JACK HIRSHLEIFER, University of California, Los Angeles and

J. W. MILLIMAN, Indiana University

Water Policy and Economic Optimizing: Some Conceptual Problems in Water Research

S. V. CIRIACY-WANTRUP, University of California, Berkeley

Discussion: ROBERT H. HAVEMAN, Grinnell College

M. MASON GAFFNEY, University of Wisconsin, Milwaukee

ARTHUR MAASS, Harvard University

8:30 A.M. THE MEASUREMENT OF PRICE CHANGE

Chairman: DANIEL BRILL, Board of Governors, Federal Reserve System

Papers: Some Significant Results from the Study of International Price Competitiveness

IRVING B. KRAVIS, University of Pennsylvania and ROBERT E.

LIPSEY, National Bureau of Economic Research

The Construction of Industrial Price Indexes

JAMES K. KINDAHL, University of Chicago

Measurement of Price and Quality Changes in Consumer Capital Goods

PHOEBUS J. DERYMES, University of Pennsylvania

Discussion: DOROTHY S. BRADY, University of Pennsylvania

GREGORY KIPNIS, National Industrial Conference Board

8:30 A.M. CONDITIONS FOR TECHNOLOGICAL PROGRESS AND ECONOMIC GROWTH IN COMMUNIST CHINA (Joint Session with the Association for the Study of Soviet-type Economies)

Chairman: ALEXANDER ECKSTEIN, University of Michigan

Papers: Role of Development Policies and Economic Organization in Innovation and Growth

EDWIN F. JONES, Department of State

Incentive Policies and Technological Progress in Agriculture

J. C. LIU, McGill University and the International Bank for Reconstruction and Development

Relationships between Foreign Trade, Innovation, and Outlook for Economic Growth

ROBERT DERNBERGER, University of Chicago

Discussion: J. M. MONTIAS, Yale University
HENRY ROSOVSKY, Harvard University

8:30 A.M. GRADUATE STUDENT PAPERS (Joint Session with *The American Economist*)

Chairman: GERHARD TINTNER, University of Southern California

Papers: A Two-Sector Growth Model with Diminishing Returns and Endogenous (Neo-Malthusian) Growth of Population

RASESH THAKKAR, University of Rochester
Stochastic Reserve Losses

ELEANOR M. BIRCH and JOHN M. HEINEKE, University of Iowa
Economic Theory and Policy Decisions: A Case Study of the Canadian Dollar since 1945

ALEX G. VICAS, Loyola College (Canada)

Discussion: MARK Z. FABRYCY, New York University

JOHN BOORMAN, University of Southern California

ERNEST J. BARTELL, Notre Dame University

10:45 A.M. POLICY ROUNDTABLE 1: SOME PROBLEMS OF FULL EMPLOYMENT (Joint Session with SSRC Committee on Economic Stability)

Moderator: R. A. GORDON, University of California, Berkeley

Panel: WALTER HOADLEY, Bank of America

WARREN L. SMITH, University of Michigan

HERBERT STEIN, Committee for Economic Development

POLICY ROUNDTABLE 2: RESEARCH AND DEVELOPMENT

Moderator: H. E. RILEY, National Science Foundation

Panel: BURTON KLEIN, RAND Corporation

ZVI GRILICHES, University of Chicago

2:30 P.M. MILITARY MANPOWER PROCUREMENT (Joint Session with Industrial Relations Research Association)

Chairman: HAROLD WOOL, U. S. Department of Defense

Papers: The Supply of Military Personnel in the Absence of a Draft

STUART H. ALTMAN, Brown University and ALAN E. FECHTER,
Institute of Defense Analysis

Re-enlistments in the U. S. Navy: A Cost Effectiveness Study

FRANKLIN M. FISHER, Massachusetts Institute of Technology
and ANTON S. MORTON, Arthur D. Little, Inc.

The Economic Cost of the Draft

WALTER Y. OT, University of Washington

Discussion: GEORGE H. HILDEBRAND, Cornell University

PAUL A. WEINSTEIN, University of Maryland

2:30 P.M. ECONOMIC DEVELOPMENT (Joint Session with Econometric Society)

Chairman: MOSES ABRAMOVITZ, Stanford University

Papers: Some Lessons of History for Developing Nations

RONDO CAMERON, University of Wisconsin

Sources of Postwar Growth in Nine Advanced Countries

EDWARD F. DENISON, Brookings Institution

Optimal Patterns of Growth in an Open Economy

HOLLIS B. CHENERY and ROBERT DORFMAN, Harvard University

Discussion: HENRY ROSOVSKY, Harvard University

CHARLES KINDLEBERGER, Massachusetts Institute of Technology

2:30 P.M. AGGREGATE MODELS

Chairman: SAMUEL H. NERLOVE, University of California, Los Angeles

Papers: Effects of Monetary and Fiscal Policies with Keynesian or Classical Demand Elasticities

CARL CHRIST, Johns Hopkins University

Policy Multipliers and the Structure of the Canadian Monetary Sector—An Econometric Analysis

HAROLD SHAPIRO, University of Michigan

Expectations and Adjustment in the Monetary Sector

EDGAR FEIGE, University of Wisconsin

Discussion: GARY FROMM, Brookings Institution

THOMAS SAVING, Michigan State University

GEORGE MORRISON, State University of New York at Buffalo

8:00 P.M. RICHARD T. ELY LECTURE

Invited Lecture: ABBA LERNER, Michigan State University and Tel-Aviv University

Wednesday, December 28, 1966

8:30 A.M. COST-BENEFIT ANALYSIS FOR GOVERNMENT DECISIONS

Chairman: WILLIAM H. MECKLING, University of Rochester

Papers: Government-Industry Development of a Commercial Supersonic Aircraft

STEPHEN ENKE, General Electric-Tempo, and JOHN WALGREEN, Office of the Secretary of Defense

An Application of Cost-Benefit Analysis to the Work-Experience Program

WORTH BATEMAN, Department of Health, Education, and Welfare

A Proposed Methodology for Comparing Federally Assisted Housing Programs

WILLIAM ROSS, U. S. Department of Housing and Urban Development

Discussion: GEORGE W. HILTON, University of California, Los Angeles

HENRY ROWEN, U. S. Bureau of the Budget

MARTIN ANDERSON, Columbia University

8:30 A.M. PROPERTY RIGHTS AND BEHAVIOR

Chairman: ARMEN A. ALCHIAN, University of California, Los Angeles

Papers: Stock vs. Mutual Savings and Loan Associations: Some Evidence of Differences in Behavior

ALFRED NICOLS, University of California, Los Angeles

Costs of Property Rights

HAROLD DEMSETZ, University of Chicago

Discussion: HOWARD KUNREUTHER, University of Chicago

ANDREW WHINSTON, Purdue University

3:30 A.M. ECONOMIC HISTORY

Chairman: ARTHUR H. COLE, Harvard University

Papers: John Law of Lauriston: Banker, Gamester, Merchant, Chief?

EARL J. HAMILTON, University of Chicago and State

University of New York at Binghamton

Government Regulation and Growth in the French Paper Industry During the Eighteenth Century

WARREN C. SCOVILLE, University of California, Los Angeles

New Light on a Statistical Dark Age: U. S. Real Output, 1800-1840?

PAUL DAVID, Stanford University

Discussion: JOHN H. DALES, University of Toronto

STANLEY ENGERMAN, University of Rochester

ROSS M. ROBERTSON, Indiana University

10:45 A.M. **POLICY ROUNDTABLE 3: GUIDEPOSTS AND INFLATION** (Joint Session with Industrial Relations Research Association)

Moderator: ALBERT REES, Princeton University

Panel: WILLIAM G. BOWEN, Princeton University
JOHN T. DUNLOP, Harvard University
OTTO ECKSTEIN, Harvard University
GEORGE SHULTZ, University of Chicago

10:45 A.M. **POLICY ROUNDTABLE 4: REGULATION OF INDUSTRY**

Moderator: NEIL H. JACOBY, University of California, Los Angeles

Panel: WILLIAM J. BAUMOL, Princeton University
JOEL DEAN, Columbia University
JOHN R. MEYER, Harvard University
GEORGE J. STIGLER, University of Chicago

12:30 P.M. **JOINT LUNCHEON: AMERICAN ECONOMIC ASSOCIATION AND AMERICAN FINANCE ASSOCIATION**

Chairman: FRITZ MACHLUP, Princeton University

Talk: Coordination of Economic Policy
ALLAN SPROUL, California

2:30 P.M. **ANTI-TRUST AND MONOPOLY**

Chairman: AARON DIRECTOR, University of Chicago

Papers: The Goals of Anti-Trust Policy

ROBERT H. BORK, Yale University
Vertical Mergers, Market Power and the Anti-Trust Laws
WILLIAM COMANOR, Harvard University
Conscious Parallelism and the Kinked Oligopoly Demand Curve
WILLIAM HAMBURGER, University of North Carolina

Discussion: PHIL C. NEAL, University of Chicago
JOHN S. MCGEE, Duke University
B. PETER PASHIGIAN, University of Chicago

2:30 P.M. **INVITED DOCTORAL DISSERTATIONS I**

Chairman: E. CARY BROWN, Massachusetts Institute of Technology

Papers: Daily Newspapers, Monopolistic Competition, and Economies of Scale

JAMES N. ROSSE (Ph.D., University of Minnesota), Stanford University

Rational Choice and Patterns of Growth in a Monetary Economy

MIGUEL SIDRAUSKI (Ph.D., University of Chicago), Massachusetts Institute of Technology

The Canadian Experience with Flexible Exchange Rates

JOHN PIPPENGER (Ph.D., University of California, Los Angeles), University of California, Santa Barbara

Discussion: HARRY EASTMAN, University of Toronto

DALE JORGENSEN, University of California, Berkeley

PETER O. STEINER, University of Wisconsin

2:30 P.M. **TOPICS IN MONEY** (Joint session with American Finance Association)

Chairman: J. FRED WESTON, University of California, Los Angeles

Papers: Some Implications of Money Supply Analysis

DAVID FAND, State University of New York at Buffalo

Keynes and the Keynesians: A Suggested Interpretation

A. LEIJONHUFVUD, University of California, Los Angeles

Financial Regulation and the Effectiveness of Monetary Policy

WILLIAM BRAINARD, Yale University

Discussion: ALLAN H. MELTZER, Carnegie Institute of Technology

MYRON ROSS, Western Michigan University
E. J. KANE, Boston College

8:00 P.M. PRESIDENTIAL ADDRESS

Chairman: RICHARD LESTER, Princeton University
Presidential Address: FRITZ MACHLUP, Princeton University

9:15 P.M. BUSINESS MEETING

Thursday, December 29

8:30 A.M. ECONOMICS OF HEALTH

Chairman: JOSEPH J. SPENGLER, Duke University
Papers: The Allocation of Research Among Diseases
SIMON ROTTENBERG, Duke University
The Economics of Hospital Systems: Peak Loads and Regional Coordination
MILLARD F. LONG, University of Chicago and PAUL J. FELDS-STEIN, University of Michigan
The Economic Effects of Malaria Eradication
ROBIN BARLOW, University of Michigan
Discussion: PETER NEWMAN, Johns Hopkins University
GEORGE H. BORTS, Brown University

8:30 A.M. THE "CONVERGENCE" HYPOTHESIS: THE PLANNING AND MARKET ELEMENTS IN THE DEVELOPMENT OF SOVIET, WESTERN AND DEVELOPING ECONOMIES
(Joint Session with Association for Comparative Economics)

Chairman: GERHARD COLM, National Planning Association
Papers: From the Aspect of:
Soviet-Type Economies, ABRAM BERGSON, Harvard University
Western-Type Economies, NEIL CHAMBERLAIN, Yale University
Developing Economies, SHANTI S. TANGRI, Wayne State University
Discussion: VICTOR PERLO, Economic Consultant
ALLAN GRUCHY, University of Maryland

8:30 A.M. INVITED DOCTORAL DISSERTATIONS II

Chairman: JOE S. BAIN, University of California, Berkeley
Papers: Natural Resources, Factor Mix, and Factor Reversal in International Trade
SEIJI NAYA (Ph.D., University of Wisconsin)
Adam Smith's Theory of Justice, Prudence and Beneficence
WILLIAM F. CAMPBELL (Ph.D. University of Virginia), Louisiana State University
The Effect of State Fair Employment Laws on the Economic Position of Nonwhites
WILLIAM LANDES (Ph.D., Columbia University), University of Chicago
Discussion: O. H. BROWNLEE, University of Minnesota
RICHARD NELSON, The RAND Corporation
ANTHONY M. TANG, Vanderbilt University and the Chinese University, Hong Kong

10:45 A.M. POLICY ROUNDTABLE 5: INTERNATIONAL PAYMENTS PROBLEMS

Moderator: GOTTFRIED HABERLER, Harvard University
Panel: EMILE DESPRES, Stanford University

H. G. JOHNSON, University of Chicago and London School of Economics

PETER KENEN, Columbia University

ROBERT ROOSA, Brown Brothers Harriman and Co.

10:45 A.M. **POLICY ROUNDTABLE 6: ROLE OF GOVERNMENT IN THE ECONOMY**

Moderator: **ARTHUR F. BURNS**, Columbia University

2:30 P.M. **DAS KAPITAL: A CENTENARY APPRECIATION**

Papers: **The Marxian Model of Capital Accumulation**

ALEXANDER ERLICH, Columbia University

Marxian Economics as Economics

PAUL SAMUELSON, Massachusetts Institute of Technology

Marxian Influences in "Bourgeois" Economics

MARTIN BRONFENBRENNER, Carnegie Institute of Technology

and Center for Advanced Study in the Behavioral Sciences

Discussion: **EVSEY DOMAR**, Massachusetts Institute of Technology

DONALD GORDON, University of Rochester

SCOTT GORDON, Indiana University

2:30 P.M. **THE EFFICIENCY OF EDUCATION IN ECONOMICS**

Chairman: **G. L. BACH**, Stanford University

Papers: **Experiments in the Teaching of Elementary Economics**

BERNARD F. HALEY, University of California, Santa Cruz

The Effectiveness of Programmed Learning in Elementary Economics

KEITH LUMSDEN, Stanford University

A New "Test of Economic Understanding" for College Level Students

RENDIGS FELS, Vanderbilt University

Discussion: **WILLIAM ALLEN**, University of California, Los Angeles

DONALD PADEN, University of Illinois

PHILLIP SAUNDERS, Carnegie Institute of Technology

2:30 P.M. **TRANSPORTATION AND PATTERNS OF URBAN DEVELOPMENT**

Chairman: **JOHN R. MEYER**, Harvard University

Papers: **An Aggregative Model of Resource Allocation in a Metropolitan Area**

EDWIN MILLS, Johns Hopkins University

The Location of Economic Activity in Cities

LEON MOSES, Northwestern University and

HAROLD F. WILLIAMSON, JR., University of Illinois

Post-War Metropolitan Development: Housing Preferences and Auto Ownership

JOHN F. KAIN, Harvard University

Discussion: **JULIUS MARGOLIS**, Stanford University

BENJAMIN CHINITZ, U. S. Department of Commerce

RICHARD MUTH, Washington University

FELLOWSHIPS AND GRANTS

The Social Science Research Council's annual announcement describing fellowships and grants to be awarded in 1966-67 is now ready for distribution. It lists research training fellowships, foreign area fellowships, faculty research grants and grants for research on foreign areas. Inquiries about research training fellowships, offered to postdoctoral and advanced predoctoral candidates, and faculty research grants should be addressed to Social Science Research Council Fellowships and Grants, 230 Park Ave., New York, N.Y. 10017.

Inquiries about co-sponsored programs should be addressed to the other offices indicated. To avoid missing deadlines correspondence should be initiated no later than early October.

Foreign area fellowships for multidisciplinary predoctoral or postdoctoral training relating to Asia and the Near East, the Soviet Union and Eastern Europe, Africa, Latin America, or Western Europe are under the joint auspices of SSRC and the American Council of Learned Societies. Address inquiries to the Foreign Area Fellowship Program at 444 Madison Ave., New York, N.Y. 10022.

Grants for research on foreign areas will be offered by joint committees of SSRC and ACLS to social scientists holding the Ph.D. degree or its equivalent. Grants for research on Africa, Contemporary China, Latin America, and the Near and Middle East are administered by the SRC. Grants for Asia and for Slavic and East European Studies are administered by the American Council of Learned Societies, 345 East 46th Street, New York, N.Y. 10017.

The National Science Foundation has asked that the A.E.A. notify its members that economists are now eligible to apply for NSF Fellowships under its programs for the improvement of college science, mathematics, and engineering teaching. Fellowships available include predoctoral fellowships, postdoctoral fellowships, fellowships for college teachers, and "extramural fellowships" administered in cooperation with the Department of State in relation to the NATO nations. Fellowship applications for 1967-68 must be received by mid-October. More detailed information about all the programs may be obtained by writing to the Fellowship Section, Division of Graduate Education in Science, National Science Foundation, Washington, D.C., 20550.

The Agricultural Development Council, a nonprofit organization headed by John D. Rockefeller 3rd, is continuing in 1966-67 a program of grants to facilitate research in international agricultural development by professors of American universities. The program is supported by a grant of \$1,500,000 from the Ford Foundation.

Applications for research grants will be considered only from full-time faculty members of American universities. While projects must be supervised by grant recipients, advanced graduate students may collaborate in studies. Proposed studies should relate to the economic and human problems of agricultural development in the developing nations. Applications are entertained from economists, sociologists, anthropologists and other social scientists dealing with rural problems. Preference is given to proposals that promise to increase understanding of the process of agricultural development. Most studies involve field work in Asia, Africa or Latin America.

Applications for grants of up to \$2,500 may be submitted to the Council at any time. For grants of more than \$2,500, applications are considered three times each academic year. In the next period, applications received by October 15, 1966 will be considered for award by November 15, 1966. Requests for research grant application forms or correspondence relating to the program may be addressed to Dr. Clifton R. Wharton, Jr., Director, American Universities Research Program, The Agricultural Development Council, Inc., 630 Fifth Avenue, New York, 10020.

The American Association of University Women announces its Fellowships for American Women and its International Fellowships, 1967-68. The former are open to U.S. women, the latter to women of other countries, who hold the doctorate or who have fulfilled all requirements for the doctorate, except the dissertation. In each case, the deadline for filing is December 1, 1966. Application forms and additional information may be obtained from: Fellowships Office, AAUW Educational Foundation, 2401 Virginia Avenue, N.W., Washington, D.C., 20037.

The Inter-University Committee on Travel Grants announces opportunities for advanced graduate students, faculty members, and postdoctoral researchers to engage in study and research in the Soviet Union, Bulgaria, Czechoslovakia and Hungary during the academic

year, 1967-68. The Inter-University Committee administers three separate exchanges with the USSR: an exchange of advanced graduate students and young faculty, an exchange of postdoctoral researchers, and an exchange of American teachers of Russian for a special ten-week program during the summer. The exchanges with Bulgaria, Czechoslovakia, and Hungary are open to advanced graduate students, faculty, and postdoctoral researchers. Participants are chosen in national competition through application and interview. Participants must have proficiency in the language of the receiving country commensurate with the needs of their programs. Applicants must be American citizens and with the exception of those applying for the summer exchange of language teachers which is open also to teachers of Russian in elementary and secondary schools, applicants must be affiliated with American universities or colleges. For additional information, write: Howard Mehlinger, Inter-University Committee on Travel Grants, 021 Lindley Hall, Indiana University, Bloomington, Indiana.

NEW JOURNALS

The first issue of a new quarterly, *The Journal of Developing Areas*, will be published in September 1966. The *Journal* is intended to stimulate the descriptive and comparative study of regional development past and present with the object of promoting fuller understanding of man's relationship to the developmental process. The *Journal* is intended to be international both in its coverage and in the composition of its Board of Advisors. It will therefore welcome and consider articles from scholars in all countries. For further information, contact: The Editor, *The Journal of Developing Areas*, Western Illinois University, Macomb, Illinois 61455.

The Western Finance Association, in conjunction with the University of Washington's Graduate School of Business Administration, has announced the publication of the *Journal of Financial and Quantitative Analysis*. It is a quarterly journal and began publication with the March 1966 issue. Manuscripts should be submitted to the managing editor of the *Journal*: Stephen H. Archer, Graduate School of Business Administration, University of Washington, Seattle, Washington 98105.

A new journal, *The Appalachian Financial Review*, published its first issue in Spring 1966. It will be published annually, or more frequently, at the Graduate School of Business Administration, Duquesne University, Pittsburgh, Pennsylvania. The editor is Donald A. Fergusson, College of Business Administration, Syracuse University, Syracuse, New York.

Deaths

Mohiuddin Ahmed, air crash in Pakistan, February 1, 1966.

Wroe Alderson, Wharton School, University of Pennsylvania.

Arthur M. Borak, professor of economics, Khartoum, Sudan, January 24, 1966.

Melvin D. Brockie, associate professor of economics, California Institute of Technology, April 25, 1966.

Zenas C. Dickinson, professor emeritus of economics, University of Michigan, March 22, 1966.

Edward A. Duddy, professor emeritus of marketing, Graduate School of Business, University of Chicago, March 4, 1966.

Fred R. Fairchild, Knox professor emeritus of economics, Yale University, April 1966.

Joe S. Floyd, Jr., professor of finance, University of North Carolina.

Gilbert Goodman, assistant professor of economics, Wayne State University, May 9, 1966.

Kathleen C. Jackson, February 4, 1966.

Norris G. Kenny, Clearwater, Florida, March 14, 1966.

Harold King, Seton Hall, January 17, 1966.

Earl L. Knight, January 11, 1966.

James G. Lyne, January 16, 1966.

Leon C. Marshall, professor emeritus of economics, The American University.

Jean M. Massel, June 1965.

Robert G. Rice, assistant professor of business economics, University of Chicago, February 16, 1966.

William A. Salant, Chico, California, July 2, 1966.

Frank M. Surface, August 31, 1965.

John L. Tierney, Arlington, Virginia, May 17, 1966.

Retirements

Walter A. Baude, professor emeritus of statistics, University of Cincinnati, September 1, 1966.

Camille J. Botte, Ohio State University.

Elizabeth Brandeis, University of Wisconsin, June 1966.

Thomas W. Holland, professor emeritus of economics, George Washington University, September 1, 1966.

Hersel W. Hudson, professor of economics, College of Business Administration, Kent State University, June 1966.

Arthur D. Jacobsen, USAF.

William Jaffe, professor of economics, Northwestern University.

Ralph C. Jones, professor of economics, Yale University, July 1966.

Theodosi A. Mogilnitsky, professor and chairman of economics and finance, Loyola University, Chicago.

Lawrence H. Seltzer, professor of economics, Wayne State University, June 1966.

William R. Sherman, professor and head of department of economics and business administration, Hillsdale College, September 1965.

Rollin G. Thomas, professor of economics, Bowling Green State University.

Alva M. Tuttle, Ohio State University.

Jesse P. Watson, professor of economics, University of Pittsburgh, August 1966.

Wallace Wright, professor emeritus of economics, Iowa State University, May 30, 1965.

Visiting Foreign Scholars

Ramesh C. Bhardwaj, University of St. Andrews, Dundee, Scotland: visiting lecturer in economics, San Diego State College, 1966-67.

Micha Gisser, economist, Ministry of Agriculture, Israel: visiting associate professor of economics, Ohio State University.

William Gorman, Nuffield College, Oxford University: visiting professor of economics, Stanford University, spring and summer, 1966-67.

Donald M. Lamberton, University of New South Wales: visiting professor of economics, Stanford University, autumn 1966.

Staffan B. Linder, Stockholm School of Economics: visiting research associate in economics, Yale University, fall 1966.

Alan S. Milward, University of East Anglia, England: visiting associate professor of economics, Stanford University, 1966-67.

Ryoshin Minami, Hitotsubashi University: visiting research associate in economics, Yale University.

Yair Mundlak, Hebrew University: visiting associate professor of economics, University of Chicago, 1966-67.

Desmond H. O'Halloran, University of Dublin, Ireland: visiting lecturer in economics, Ohio State University.

Juan P. Perez Castillo, Universidad Central de Venezuela: visiting associate professor of economics, Tulane University, spring 1967.

C. Rangarajan, Indian Statistical Institute, New Delhi: visiting associate professor of finance, New York University, 1966-68.

T. N. Srinivasan, Indian Statistical Institute, New Delhi: visiting professor of economics, Stanford University, 1966-67.

Kenji Takeuchi, Kwansei Gakuin University, Japan: visiting assistant professor of economics, Lafayette College, 1966-67.

Brian R. Van Arkadie, Ministry of Overseas Development, British Government: visiting research staff economist, Yale University.

Promotions

Richard E. Attiyeh: assistant professor, department of economics, Yale University.

Eric N. Baklanoff: professor, department of economics, Louisiana State University.

Robin Barlow: associate professor, department of economics, University of Michigan.

Robert A. Barry: assistant professor, department of economics, College of William and Mary.

Yoram Barzel: associate professor, department of economics, University of Washington.

Joseph M. T. Becker: professor of economics, School of Commerce and Finance, St. Louis University.

Stanley Engerman: associate professor, department of economics, University of Rochester.

Zbigniew M. Fallenbuchl: professor, department of economics, University of Windsor.

Eugene F. Fama: associate professor of finance, Graduate School of Business, University of Chicago.

John R. Felton: associate professor, department of economics, University of Nebraska.

Belton M. Fleisher: associate professor, department of economics, Ohio State University.

John E. Floyd: associate professor, department of economics, University of Washington.

Roger N. Folsom: assistant professor, U. S. Naval Postgraduate School, Monterey, California.

Herman Freudenberger: professor, department of economics, Tulane University.

Seymour S. Goodman: associate professor, department of economics, Tulane University.

Walter Gross: professor, department of marketing, University of Georgia.

Niles M. Hansen: associate professor, department of economics, University of Texas.

W. Lee Hansen: professor, department of economics, University of Wisconsin.

Van Court Hare: associate professor, Graduate School of Business, Columbia University.

Robert Hawkins: assistant professor, Graduate School of Business Administration, New York University.

George W. Hilton: professor, department of economics, University of California, Los Angeles.

Samuel P. S. Ho: assistant professor, department of economics, Yale University.

Leon Hollerman: professor, department of economics, Claremont Men's College.

Alphonse G. Holtmann: associate professor, department of economics, Wayne State University.

Ching-Yao Hsieh: associate professor, department of economics, George Washington University.

Stephen H. Hymer: associate professor, department of economics, Yale University.

Michael D. Intriligator: associate professor, department of economics, University of California, Los Angeles.

M. Bruce Johnson: associate professor, department of economics, University of Washington.

Ronald Jones: professor, department of economics, University of Rochester.

Anne O. Krueger: professor, department of economics, University of Minnesota.

James W. Kuhn: professor, Graduate School of Business, Columbia University.

James W. Land: assistant professor, department of economics, Yale University.

Robert J. Lawrence: associate professor, department of economics, University of Texas.

Wilford L. L'Esperance: associate professor, department of economics, Ohio State University.

Harold F. McClelland: professor, department of economics, Claremont Men's College.

Rodney Morrison: assistant professor, department of economics, Wellesley College.

Walter Y. Oi: professor, department of economics, University of Washington.

Van Doorn Ooms: assistant professor, department of economics, Yale University.

Rudolph Penner: associate professor, department of economics, University of Rochester.

George E. Rejda: associate professor, department of economics, University of Nebraska.

Fred Renwick: assistant professor of finance, Graduate School of Business Administration, New York University.

Clark W. Reynolds: associate professor, department of economics, Yale University.

Karl W. Roskamp: professor, department of economics, Wayne State University.

Gian S. Sahota: associate professor, department of economics, Vanderbilt University; at University of São Paulo, Brazil, 1966-67.

Thomas R. Saving: professor of economics, Michigan State University.

Jeffrey M. Schaefer: assistant professor, department of economics, Rutgers—The State University.

Gerhard Schmidt: associate professor, Fairleigh Dickinson University.

William G. Shepherd: associate professor, department of economics, University of Michigan.

Gordon Shillinglaw: professor, Graduate School of Business, Columbia University.

Abraham Shuchman: professor, Graduate School of Business, Columbia University.

Frederick T. Sparrow: associate professor, department of political economy, Johns Hopkins University.

Robert M. Stern: professor, department of economics, University of Michigan.

William J. Stober: associate professor, department of economics, Louisiana State University.

- Boris Swerling: professor of economics, Georgetown University,
 Ronald L. Teigen: associate professor, department of economics, University of Michigan.
 Judith G. Thornton: associate professor, department of economics, University of Washington.
 George W. Ulseth: professor, department of economics, Wisconsin State University.
 Ranbir Varma: professor, department of economics, Long Island University.
 Harold Watts: professor, department of economics, University of Wisconsin.
 James H. Weaver: associate professor, department of economics, The American University.
 Burton Weisbrod: professor, department of economics, University of Wisconsin.
 Jacob Weissman: professor, department of economics, Hofstra University.
 Joseph T. White: assistant professor, department of economics, Georgetown University.
 Marina Von N. Whitman: associate professor, department of economics, University of Pittsburgh.
 John H. Wicks: associate professor, department of economics, University of Montana.
 Dean A. Worcester: professor, department of economics, University of Washington.

Administrative Appointments

- William R. Allen: vice chairman, department of economics, University of California, Los Angeles.
 Robert F. Barlow, dean, Whittemore School of Business and Economics: academic vice-president, University of New Hampshire.

Muhammad A. Rahman, University of Hawaii: visiting research associate, department of economics, Yale University.

Denis T. Raihall: assistant professor, College of Business and Economics, University of Delaware.

Kadiyala K. Rao: assistant professor, department of economics, Wayne State University.

J. F. Reichert, Royal Military College: instructor, department of economics and commerce, Simon Fraser University.

L. Winston Ring: assistant professor of marketing, Graduate School of Business, Columbia University.

R. Richard Ritti: associate professor of behavioral science, Graduate School of Business, Columbia University.

Alice Rivlin, Brookings Institution: deputy assistant secretary for program coordination, Department of Health, Education and Welfare.

Kong Kyun Ro: visiting assistant professor, department of economics, University of Pittsburgh.

Sidney E. Rolfe: visiting professor, New School for Social Research.

Paul Roman: assistant professor, department of economics, St. Louis University.

Murray N. Rothbard: associate professor, department of economics, Polytechnic Institute of Brooklyn.

Jerome Rothenberg: professor, department of economics, Massachusetts Institute of Technology.

Thomas J. Rothenberg, Northwestern University: acting associate professor, department of economics, University of California, Berkeley.

Dick Rottman, Arizona State College: associate professor of insurance, University of Arkansas.

Nancy Ruggles, Yale University: research staff member, National Bureau of Economic Research.

Richard Ruggles, Yale University: research staff member, National Bureau of Economic Research.

Emiko Sakurai, University of Iowa: assistant professor of management, University of Arkansas.

Joan Sato: assistant professor, department of economics, University of New Mexico.

Richard Schramm: assistant professor of banking and finance, Graduate School of Business, Columbia University.

Carl C. Schwan, Jr., Vanderbilt University: research department, Industrial Nucleonics Corporation, Columbus, Ohio.

Stuart O. Schweitzer: assistant professor, department of economics, Wayne State University.

Thomas T. Sekine, University of Birmingham: assistant professor, department of economics and commerce, Simon Fraser University.

Donald E. Sexton, Jr.: assistant professor of operations research, Graduate School of Business, Columbia University.

David L. Shapiro: acting assistant professor, department of economics, University of California, Los Angeles.

Edward Shapiro, University of Detroit: associate professor, department of economics, Wayne State University.

Judith C. Shapiro, London School of Economics: assistant professor of economics, University of Washington.

Ansel M. Sharp, Oklahoma State University: economic advisor, Ministry of Planning and Development, Kenya, Africa.

Lawrence H. Shaw: assistant professor of economics, Vanderbilt University.

Arthur S. Shenfield: visiting professor of economics, Graduate School of Business, University of Chicago, autumn quarter 1966.

James Sherbaniuk, University of Manitoba: assistant professor, department of economics and commerce, Simon Fraser University.

Jagdish N. Sheth: assistant professor of marketing, Graduate School of Business, Columbia University.

Joseph Shister, State University of New York at Buffalo: member of the New York State Board of Mediation.

Robert D. Shriner, University of Oklahoma: research associate, Division of Business and Economic Research, University of Wyoming.

Ammar Siamwalla: research staff economist, department of economics, Yale University.

Alvin J. Silk: assistant professor of marketing, Graduate School of Business, University of Chicago.

Larry D. Singell, Bowling Green State University: assistant professor, department of economics, Wayne State University.

Neil M. Singer, assistant professor of economics, University of Maryland.

Arthur A. Sloane: associate professor, College of Business and Economics, University of Delaware.

Alan Sorkin: lecturer, department of economics, Goucher College.

Jean-Robert Spichiger: assistant professor in economics, University of Puerto Rico.

Robert N. Stearns, Yale University: instructor in economics, Ohio State University.

Frank G. Steindl, Oklahoma State University: visiting research economist, Federal Reserve Bank of Cleveland, 1966-67.

Matthew A. Stephenson: assistant professor, department of economics, College of Business, Virginia Polytechnic Institute.

Daniel E. Strayer: instructor in economics, U.S. Air Force Academy.

W. Craig Stubblebine: associate professor of economics, Claremont Men's College.

J. Dirck Stryker: research staff economist and lecturer, department of economics, Yale University.

Sam Sydneysmith, North Carolina State University: assistant professor, department of economics and commerce, Simon Fraser University.

Russel A. Taussig: associate professor of accounting, Graduate School of Business, Columbia University.

Phillip Taylor, Lamar State College of Technology: assistant professor of general business, University of Arkansas.

Henry Thomassen: associate professor of economics, Emory University.

Edgar H. Thornber: research associate, Graduate School of Business, University of Chicago, July 1, 1966.

George S. Tolley, North Carolina State College: professor, department of economics, University of Chicago.

John F. Trainor: instructor in economics, Washington State University.

A. Dale Tussing: assistant professor of economics, Syracuse University.

Dan Usher: assistant professor of economics, Graduate School of Business, Columbia University.

J. F. Vallery, Jr., University of Tennessee: lecturer, department of economics, University of Alabama.

John M. Vernon: assistant professor, department of economics, Duke University.

Hugh D. Walker, Vanderbilt University: assistant professor of economics, Indiana University.

Gary Walton, University of Washington: assistant professor of economics, Ohio State University.

Leon Wegge: department of economics, University of California, Davis.

William D. Wells: professor of psychology and marketing, Graduate School of Business, University of Chicago.

Harold R. Williams, University of Nebraska: assistant professor of economics, College of Business Administration, Kent State University.

T. David Williams, Northwestern University: lecturer in economics, University of Malawi.

Charles R. Wolf: assistant professor of banking and finance, Graduate School of Business, Columbia University.

Robert J. Wolfson: professor of economics, Syracuse University.

Henry W. Woudenberg, Jr., Michigan State University: assistant professor of economics, College of Business Administration, Kent State University.

Kunio Yoshihara: assistant professor, department of economics: University of Michigan.

John P. Young, Division of Finance, Department of State: visiting professor of economics, Claremont Men's College, 1966-67.

David B. Zenoff: assistant professor of international business, Graduate School of Business, Columbia University.

John A. Zerby: lecturer, department of economics, University of Sydney, Australia.

Leaves for Special Appointments

Kenneth J. Arrow, Stanford University: visiting professor of economics, Massachusetts Institute of Technology, autumn 1966-67.

Werner Baer, Vanderbilt University: professor, Faculty of Economics, University of São Paulo, Brazil, 1966-67.

Donald C. Bartholomew, University of Missouri at Kansas City: program economist, Seoul, Korea, 1966-67.

Barbara Bergmann, University of Maryland: Administration for International Development, 1966-67.

Edward C. Budd, Pennsylvania State University: Office of Business Economics, U.S. Department of Commerce, 1966-67.

Carl F. Christ, Johns Hopkins University: visiting professor, University of Essex, England, 1966-67.

Joseph S. Chung, Illinois Institute of Technology: Fulbright lecturer, Seoul National University, Korea, 1966-67.

Roger Dehem, Laval University: visiting professor, department of economics, Queen's University, autumn 1966-67.

William G. Dewald, Ohio State University: consultant, Reserve Bank of Australia, Sydney.

James E. Dugan, University of Colorado: Fulbright lecturer, Liberia, 1966-67.

Robert A. Flammang, Louisiana State University: visiting professor of economics, National University of the South, Bahia Blanca, Argentina, spring 1967.

Walter Galenson, University of California, Berkeley: visiting professor of economics and industrial and labor relations, Cornell University, 1966-67.

Ronald B. Gold, Ohio State University: Harvard University project, AID, Chilean Ministry of Finance.

Seymour S. Goodman, Tulane University: visiting associate professor of economic development, University of Istanbul, Turkey, spring 1967.

Douglas H. Graham, Vanderbilt University: professor of economics, Vargas Foundation, Rio de Janeiro, 1966-67.

Gerald K. Helleiner, University of Toronto: senior research fellow and director, Economic Research Bureau, University College, Dar es Salaam, Tanzania, 1966-67.

William F. Hellmuth, Oberlin College: research professor and director, Economic Research Bureau, University College, Dar es Salaam, Tanzania, February-August 1966.

Bert Hoselitz, University of Chicago: visiting professor, University of California, Santa Cruz, winter quarter 1966-67.

Paul Luey, University of Hong Kong: visiting fellow, department of economics, Research School of Pacific Studies, Australian National University, June to November 1966.

Roland N. McKean, University of California; Los Angeles: visiting professor, Harvard University, second semester.

George G. S. Murphy, University of California, Los Angeles: visiting senior lecturer, University of Colchester, Essex, 1966-67.

J. Carter Murphy, Southern Methodist University: special field staff, Rockefeller Foundation, Bangkok, Thailand, 1966-67.

Sam Peltzman, University of California, Los Angeles: National Bureau of Economic Research, New York, 1966-67.

Joseph D. Phillips, University of Illinois: Harvard Advisory Group, Buenos Aires, 1966-68.

David Robinson, University of Arkansas: Fulbright lecturer, Finland, 1966-67.

Marvin E. Rozen, Pennsylvania State University: senior research adviser, Pakistan Institute of Development Economics, 1966-68.

Gian S. Sahota, Vanderbilt University: professor of economics University of São Paulo, Brazil, 1966-67.

Frederic C. Shorter, Princeton University: social science consultant, Ford Foundation in Turkey.

Robert F. Smith, Louisiana State University: curriculum director, American Institute for Free Labor Development program for South American labor specialists, Loyola University, 1966-67.

Anthony M. Tang, Vanderbilt University: visiting professor of economics, Chinese University of Hong Kong, Vanderbilt Overseas Professorship Program.

Milton C. Taylor, Michigan State University: fiscal adviser to the government of Nigeria, research and graduate instruction, University of Ibadan, 1966-67.

Joseph M. Thorson, Southern Illinois University: to organize a business school at the University of Liberia, under the auspices of Cornell University's AID program, 1966-68.

Oliver E. Williamson, University of Pennsylvania: special economic adviser to the Assistant Attorney General.

Resignations

Richard Ablin, State University of New York at Buffalo.

David S. Ball, Vanderbilt University.

John M. Brazzel, U.S. Air Force Academy, December 1965.

Willard Carleton, New York University.

Robert S. Carlson, Graduate School of Business, Columbia University.

Eaton H. Conant, Graduate School of Business, University of Chicago, August 31, 1966.

Gerald L. Duskin, Rutgers—The State University.

Daniel O. Fletcher, Ohio State University.

Harold W. Fox, Rutgers—The State University.

Peter G. Franck, Robert College, Istanbul.

Lewis P. Freitas, Graduate School of Business, Columbia University.

Donald F. Gordon, University of Washington.
David G. Greene, Rutgers—The State University.
Randall B. Haydon, Kent State University, August 1966.
Claude Hillinger, State University of New York at Buffalo.
Charles T. Horngren, Graduate School of Business, University of Chicago, June 30, 1966.
Eugene Lerner, Graduate School of Business Administration, New York University.
Meno Lovenstein, Ohio State University.
W. David Maxwell, Tulane University.
Jora R. Minasian, State University of New York at Buffalo.
Wayne L. Mock, Graduate School of Business, Columbia University.
A. Monroe Moore, Rutgers—The State University.
Richard F. Muth, Graduate School of Business, University of Chicago.
Dominic F. O'Keefe, School of Commerce, New York University, September 1, 1966.
Edward F. Renshaw, University of North Carolina.
Rubin Saposnik, State University of New York at Buffalo.
Ira O. Scott, Jr., Graduate School of Business, Columbia University.
George B. Simmons, Graduate School of Business, Columbia University.
William Swift, Temple University.
J. Van Fenstermaker, Kent State University, July 1966.
Theodore Voyadjis, State University of New York at Buffalo.

Miscellaneous

Jacob Marschak, emeritus professor of economics and business administration, University of California, Los Angeles, recalled to service, 1966-67.
Dudley F. Pegrum, emeritus professor of economics, University of California, Los Angeles, recalled to service, 1966-67.

SIXTY-THIRD LIST OF DOCTORAL DISSERTATIONS IN POLITICAL ECONOMY IN AMERICAN UNIVERSITIES AND COLLEGES

The present list specifies doctoral degrees conferred during the academic year terminating June 1966. Abstracts of many of the dissertations are supplied. This list excludes theses undertaken in the same period.

General Economics; Methodology

LAWRENCE A. BOLAND, Ph.D. Illinois 1966. On the methodology of capital theory.

Price and Allocation Theory; Income and Employment Theory; History of Economic Thought

AEEMAD M. AL-SAMARRIE, Ph.D. George Washington 1966. Inequality of the size distribution of family money income: interstate comparison.

The dual aims of this study are to explain interstate variations in income inequality in 1949 and 1959, and to analyze the resulting changes in income concentration during this period. Income inequality is measured by Gini's concentration ratio, as based on the Lorenz Curve. Income refers to pretax money income received by families in each of the 48 states of the continental United States and the District of Columbia, published in the *United States Census of Population*, 1950 and 1960. Among the ten explanatory variables tested in a cross-section analysis, using a linear multiple-regression correlation model, five are found to be significantly related to the regional variations in income concentration: property income as per cent of total personal income; the proportion of total income originating in agriculture; the level of education measured by the median school years completed by adult persons; the proportion of nonwhite persons in state population; and the extent of labor participation in the state economy measured by per capita civilian employment. There was a tendency for the states to become more similar in the size distribution of their family incomes during the 'fifties, and this convergence phenomenon is associated with comparable movements in several other key state economic and demographic variables.

HIROSHI ATSUMI, Ph.D. Rochester 1966. The efficient capital accumulation in open models.

It is proved that a balanced growth path with maximal sustainable consumption has the normative significance that, if society maximizes the sum of per capita utility over time, then every optimal path converges to this balanced path. Open-growth models with labor force explicit, such as a neoclassical model, Mrs. Robinson's simple model, and a dynamic Leontief model, are used in the analysis.

RICHARD E. ATTIEYEH, Ph.D. Yale 1966. Estimation of a fixed coefficients vintage model of projection.

ALBERT BOOKBINDER, Ph.D. Fordham 1966. Money and *ex ante* investment as determinants of aggregate demand.

RONALD BRITTO, Ph.D. Brown 1966. Linear programming and the theory of investment.

ANTONIO CAMACHO, Ph.D. Minnesota 1965. Alternative concepts of informational efficiency in resource allocation mechanisms.

ANTHONY S. CAMPAGNA, Ph.D. Rutgers—The State University 1966. Expectations and the investment function.

An empirical study attempts to integrate expectations into an investment function via a model of investment appropriations as opposed to the more usual investment expenditures. Cross-section firm data of capital appropriations provided by the National Industrial Conference Board for the years 1956 and 1961 for seven industries are used to examine statistically the importance of selected financial variables in explaining capital appropriations.

M. V. CHARI, Ph.D. New York (Buffalo) 1966. Technical progress, production functions and economic growth.

The existing literature on one-sector growth models appears to suggest that unless technical progress is Harrod-neutral, it is impossible for the economy to exhibit steady proportionate growth in the long run. The present research attempts to investigate the shape and form of aggregate production function which would enable the system to exhibit steady proportionate growth even when the conditions of Harrod neutrality are not satisfied. Its equilibrium characteristics and the economic implications are critically evaluated. The analysis is extended to include the possibilities of nonexponential growth in technology and labor force.

GILBERT A. CHURCHILL, Ph.D. Indiana 1966. Location and its relation to output: a sensitivity analysis.

BRUNO CONTINI, Ph.D. Carnegie Inst. Technology 1966. Models of restricted bargaining for organizations with multiple objectives.

This concerns the design of a resource allocation decision-making scheme for organizations that have partially conflicting objectives. The particular method examined is a restricted bargaining approach which yields an unambiguous solution with the following properties: (1) it is reached by spontaneous agreement among the group members; (2) it is Pareto-optimal; (3) it guarantees a lower bound to each individual's utility. The basic idea of the method is to provide incentive for all group components to engage in a bargaining process that consists of making concessions from an initial set of demands until agreement is reached. A mathematical model is formulated and examined in terms of its implications for organizational behavior and problems of market equilibrium in an exchange economy.

JOHN A. COUGHLAN, Ph.D. Catholic 1965. The contributions of Frank Albert Fetter (1863-1949) to the development of economic theory.

MICHAEL DAVENPORT, Ph.D. Pennsylvania 1965. Corporate savings behavior: a cross-section analysis.

MICHAEL EISNER, Ph.D. Wisconsin 1965. William Morris Leiserson: economics in action.

MOHAMED EL-HODIRI, Ph.D. Minnesota 1966. Optimality criteria of economic growth as examples of optimal resource allocation over time.

A micro-economic model of growth is formulated. Optimality here means maximizing a functional whose arguments are the integral of an instantaneous utility function over time and (variable) terminal time and stocks, subject to feasibility. Under concavity and independence optimality implies the existence of a price-rental path such that producers always maximize instantaneous profits. This is shown by using ancient results from calculus of variations. Existence of an optimal program is also established.

JAMES P. GANDER, Ph.D. California (Berkeley) 1966. Economics of the growth of the firm.

MALCOLM S. GOLDEN, Ph.D. Claremont 1966. A review of major themes in the structural unemployment hypothesis: an empirical investigation of the disaggregated manufacturing sector, 1948-1960.

The postwar behavior pattern of production-worker employment in U.S. manufacturing reveals a diverse pattern. One group of industries has been relatively stagnant or has experienced an irregularly declining employment trend; another group has achieved an upsurge in employment. The object of this study is to seek an explanation for that employment diversity by analyzing the three major arguments by advocates of structural unemployment: (1) technological change; (2) demand transformation; and (3) market power.

RICHARD GONCE, Ph.D. Wisconsin 1966. The development of John R. Commons system of thought.

MICHAEL J. GOOTZEIT, Ph.D. Purdue 1966. The Corn Laws and Ricardian economics: a modern treatment.

NILS H. HAKANSSON, Ph.D. California (Los Angeles) 1966. Optimal investment and consumption strategies for a class of utility functions.

ROBERT J. HALL, Ph.D. Iowa 1966. A multi-stage model of the firm.

ROBERT S. HOLBROOK, Ph.D. California (Berkeley) 1965. Alternative models of consumer behavior: the permanent income hypothesis and the life cycle hypothesis.

YOUNG P. JOUN, Ph.D. Washington 1966. The demand for air travel.

A theory of demand incorporating time and money budget constraints is formulated to estimate airline passenger demand. An estimating model is constructed and least-squares estimates are made utilizing both time series and cross-section data. Price elasticity is found to be greater than one, and income elasticity to be close to unity.

JOHN G. KEANE, Ph.D. Pittsburgh 1965. Analysis of United States beer demand 1935-1964 with emphasis on 1945-1961.

CHULSOON KHANG, Ph.D. Minnesota 1965. A neoclassical growth model of a resource-poor open economy.

BILLY F. KIKER, Ph.D. Tulane 1965. The concept of human capital in the history of economic thought.

To measure the wealth-producing factor "human capital" requires a unit of measurement and since most economic values are measured in terms of money, a number of economists are assigning monetary values to human beings. They are, moreover, attempting to determine precisely what investment activity comprises human-capital formation, and to set forth an analytical framework within which the concept may be investigated. A survey of the literature reveals that this concept is not new. Beginning with William Petty, the literature has been investigated to determine primarily who considered human beings as capital and the motives and procedures for valuing them in monetary terms. An attempt has been made to sketch the history of the philosophy underlying such evaluation.

FENG Y. LEE, Ph.D. Michigan State 1965. Econometric analysis of the demand for basic living materials in Japan.

RICHARD E. LEVITAN, Ph.D. Harvard 1966. Demand in an oligopolistic market and theory of rationing.

ROLF R. MANTEL, Ph.D. Yale 1966. Toward a constructive proof of the existence of equilibrium in a competitive economy.

THOMAS H. MAYOR, Ph.D. Maryland 1965. The sources of decline in the United States capital-output ratio, 1869-1958.

The real aggregate capital-output ratio from 1869-1958 was reasonably stable except for a relatively brief interval after the 1920's when the ratio fell significantly. Neither capital-saving technological progress nor changes in the supply of saving—two popular hypotheses—appears able to explain the decline. More important are changes which affected the user cost of capital—increases in the relative price of capital goods, in the rate of depreciation, and especially in the tax rate.

JOHN L. MCENTAFFER, Ph.D. Boston College 1965. A theoretical and statistical analysis of the effects of changes in income distribution in the U.S. on the consumption function.

The thesis attempts to measure the impact of changes in family income distribution since 1950 on several recently fitted quarterly consumption functions. Eight measures of income distribution were added as final independent variables to three aggregate consumption functions closely related to the absolute and relative income hypotheses. Some income distribution variables significantly reduce the unexplained variation in consumption. The thesis also contains a review of aggregate consumption theory and early attempts to measure and illustrate income distribution changes.

ALI I. MEDANI, Ph.D. California (Berkeley) 1965. Constant vs. nonconstant production elasticities among firms.

YASUO MURATA, Ph.D. Stanford 1965. Embodied technical progress in a multisectoral economic growth model.

This dissertation extends the substitution theorem to a dynamic system where capital goods are classified not only in terms of kind but also in terms of vintage, assuming that each industry has a Cobb-Douglas type of production function. Then the existence of a unique balanced growth of production is proved both in abstraction from technical change and in case of technical progress.

KEITH PHILLIPS, Ph.D. Washington 1965. Some tests of simple aggregate expenditures models.

This study utilizes modern econometric methods to test the predictive power of a naive quantity theory as compared to a simple expenditures model of aggregate economic activity. On the basis of the evidence the former is clearly preferable.

J. EUGÈNE POIRIER, Ph.D. Yale 1966. Planning economic growth capital-labor substitution and foreign-aid.

JOEL POPKIN, Ph.D. Pennsylvania 1965. Interfirm difference in direct-investment behavior of U. S. manufacturers.

JOHN E. ROYLE, Ph.D. Western Reserve 1966. Short-run cost and supply curves in automation and implications for the theory of the firm.

A presentation of short-run cost behavior in automation, and a consideration of the industrial conditions of automated production. The consequences of automation on pricing and competition are also discussed.

EYTAN SHESHINSKI, Ph.D. Mass. Inst. Technology 1966. Essays on the theory of production and growth.

CALVIN D. SIEBERT, Ph.D. California (Berkeley) 1966. A micro-econometric study of fixed capital investment behavior.

MARVIN R. SNOWBARGER, Ph.D. Michigan 1966. An interaction analysis of consumer durable expenditures.

PHILIP E. SORENSEN, Ph.D. California (Berkeley) 1966. Edgeworth on monopoly, taxation, and international trade.

MATTHEW A. STEPHENSON, Ph.D. Tulane 1965. The role of technological change in the English Classical school of economics.

This study examines the view of the English Classical economists from Adam Smith to John Stuart Mill on technological change and the movement of the economy toward a stationary state where capital accumulation and population growth cease. Ricardo's view that technology did not prevent historically diminishing returns to labor and capital in agriculture is compared with the emphasis on technology of the other Classicists.

DAVID W. STEVENS, Ph.D. Colorado 1965. Capital as a determinant of economic growth: allocation in a tri-ethnic community

IAN A. STEWART, Ph.D. Cornell 1966. A quarterly econometric model of the Canadian economy 1951-1962.

After a review of the actual events of the period and of the literature pertaining to the workings of fluctuating exchange rate systems a model containing 51 endogenous variables is estimated by two-stage least-squares. Impact multipliers are derived from the model and a test run of the model's ability to generate the course of endogenous variables over a thirteen quarter intra-sample period. Simulations are run of various alternative policies over the 1958 to 1961 period.

VINCENT TARASCIO, Ph.D. Rice 1966. Pareto's methodological approach to economics: a study in the history of some scientific aspects of economic thought.

The purpose of this study is to establish the place of Vilfredo Pareto in the contemporary methodological issues of his time, and to evaluate his contribution toward making economics more scientific. The major conclusion of this study is that the economics profession has, to a remarkable extent, adopted Pareto's methodology. This contribution has been implicitly recognized in evaluations of Pareto's work but has not heretofore been accorded the explicit attention it deserves.

MAU S. TSAI, Ph.D. Southern Illinois 1966. Models of optimal bond investment decision under uncertainty.

For each bond in the portfolio, the author determines the quantities to buy, to sell and to hold in each of a sequence of time periods. The models are dynamic quadratic programming models. The possible objectives of the investor are specified, the initial prices and coupon rates on the bonds are assumed known and so are the future prices and their probabili-

ties. After the optimal quantities to buy, to sell and to hold are found, the author discusses the properties of the solutions.

ANDREW G. VERZILLI, Ph.D. Boston College 1965. Explanation of net new appropriations for expenditures on new plant and equipment for total manufacturing.

This thesis tests the hypothesis that variables which have been used to explain actual expenditures on new plant and equipment can be used to explain the variation in net new capital appropriations. The period tested is 1953 through 1962.

THAYER H. WATKINS, Ph.D. Colorado 1965. A generalized naive model for the variables of the national income accounts.

Economic History; Economic Development; National Economies

MANUEL AVILLA, Ph.D. Pennsylvania 1965. Interregional inequalities and economic underdevelopment.

JOHN D. BOYD, Ph.D. Washington 1966. Technological change, population growth and the distribution of income between developed and underdeveloped countries.

This study attempts to provide empirical content for a formal theoretical analysis of the effect of growth on the terms of trade. It finds, under reasonable assumptions about real world parameters, that a world-wide increase in real output of one per cent will result in an increase of real income of no less than .9 of one per cent in the underdeveloped nations.

MARIO S. BRODESOHN, Ph.D. Harvard 1966. A multiregional input-output analysis of the Argentine economy.

MUWAFFAK C. CHALLAH, Ph.D. Oklahoma 1965. Economic development and planning in Syria, 1950-1962.

JOHN H. CHAPMAN, Ph.D. Colorado 1965. The effects of trade pattern changes on regional input-output analysis.

CHRISTOPHER K. CLAGUE, Ph.D. Harvard 1966. Economic efficiency in Peru and the United States.

FRANCISCO DE NADAL, Ph.D. Boston College 1966. The industrial development corporation, a case study: the National Institute of Industry in Spain.

JORGE FREYRE, Ph.D. Yale 1966. External and domestic financing in the economic development of Puerto Rico; analysis and projections.

ALAN G. GREEN, Ph.D. Harvard 1965. Regional aspects of Canada's economic growth.

JOSÉ S. GUTIERREZ, Ph.D. Iowa (Ames) 1966. Regression analysis of cross-section survey data for planning an evaluation of economic development programs.

RICHARD HYSE, Ph.D. New York 1966. Economic factors in the unification of sovereign states.

JACK L. KNUSEL, Ph.D. Colorado 1965. An analysis of German development aid.

YOON T. KUARK, Ph.D. Minnesota 1966. A comparative study of economic development between South and North Korea during the post-Korean war period.

The economic development contrasts between free South and communist North Korea are examined by comparing the growth rates of national income, industrial outputs, capital formation and finance, and by comparative performances in individual industries covering agriculture, mining, manufacturing, electric power, transportation, education and foreign trade. Also included are analyses of production functions of individual industries (South Korea alone), sources and uses of foreign aid and the comparison of standards of living.

PONG S. LEE, Ph.D. Yale 1966. The doctrine of balanced growth: with special reference to Japan, 1878-1918.

MEIR MERHAV, Ph.D. New School 1966. Technological dependence, monopoly and the limits to capitalist growth.

DAVID J. MISHKIN, Ph.D. Illinois 1966. The American colonial wine industry: an economic interpretation.

EDWARD H. MOSCOVITCH, Ph.D. Mass Inst. Technology 1966. Urban-rural investment allocation in Venezuela.

FRANCIS MWIHIA, Ph.D. Pittsburgh 1965. Decision rules for optimal tax policy with illustrations from Kenya's experience as to their practical application.

PHILIP A. NEHER, Ph.D. Brown 1966. Multisector models of economic growth with applications to the Latin American experience.

The single sector, neoclassical model of economic growth is extended to the small open economy which can trade securities at a fixed rate of interest. Interest payments and receipts are accounted for, so domestic product and national income are separately distinguished. Their ratio converges in the limit if certain stability conditions are met. Self-excitation of a borrowing-repaying-lending sequence is a consequence of certain imbalanced growth states.

SE-HARK PARK, Ph.D. Washington (St. Louis) 1965. An analysis of regression estimators for urban employment multipliers and their application to the employment impact of the aerospace industry in the St. Louis SMSA.

The primary purpose of the study is to develop a framework for urban employment multiplier analysis, and to estimate, through multiple regression and correlation differential employment impacts on the St. Louis SMSA economy resulting from monthly variations in the activity levels of major export industries and the area investment sector during the period of January 1958 to June 1964.

RICHARD W. PARKS, Ph.D. California (Berkeley) 1965. An econometric model of Swedish economic growth, 1861-1955.

RAMANBHAI C. PATEL, Ph.D. Southern California 1966. Applications for stochastic processes to economic development.

BARRY W. POULSON, Ph.D. Ohio State 1965. Value added in manufacturing, mining, and agriculture in the American economy from 1809 to 1839.

This study may be viewed as a first step toward a comprehensive measure of the growth of the American economy from 1809 to 1839. Because of the nature of the data the study is confined to the three principal commodity-producing sectors—manufacturing, agriculture, and mining. The measure of performance used is value added which is defined as the value of output to producers' prices less the value of materials and fuels directly consumed in production at delivered prices.

RICHARD T. PRATT, D.B.A. Indiana 1966. Theory of income generation in a region.

ROBERT W. RAYNSFORD, JR., Ph.D. Harvard 1966. The German experience with development aid, 1956-1965.

THEODORE P. SCHULTZ, Ph.D. Mass. Inst. Technology 1966. The distribution of personal income: case study The Netherlands.

BHEKH, B. THAPA, Ph.D. Claremont 1966. Planning for development in Nepal: a perspective for 1965-80.

Economic development is a recent phenomenon in Nepal, introduced after the successful revolution in 1951. Isolation from the rest of the world prior to this event left most Nepalese unaware of the changes that had taken place outside their borders over the past century. This dissertation represents an effort to fill the need for a long-run perspective plan for Nepal, within which short-run plans may be formulated.

ARLON R. TUSSING, Ph.D. Washington 1966. Employment and wages in Japanese industrialization: a quantitative study of Yamanashi Prefecture in the Meiji era.

This study provides the first comprehensive figures on employment and wages for an important part of Japan, 1868-1908. It develops a superior method for estimating total labor force in a preindustrial society and relates intensive use of labor force to growth.

HUGH E. URBANTEK, Ph.D. Houston 1966. The United East India Company in the seventeenth century: a twentieth century prototype.

The writer describes the history of the United East India Company in relation to the

Dutch economic environment of the seventeenth century. In examining the early development of the Dutch East India Company, he reviews the international trade potentials of the sixteenth century; the economic analytical techniques; economic analysis and economic institutions; and existing managerial, financial and productive market structures.

WILLIAM R. BAILEY, Ph.D. George Washington 1966. An appraisal of input-output analysis based on a documentation of the interindustry relations study for 1947.

The 1947 input-output program of the federal government is thoroughly documented, and the estimates derived from the various models developed during the program are published for the first time. The quality of the estimates is analyzed in terms of the structure and the empirical content of the models, and this analysis is integrated with other important analyses of the input-output method. Finally, it is shown that the effectiveness of a general model of national income formation can be enhanced by incorporation with an input-output model.

JERALD R. BARNARD, Ph.D. Iowa (Ames) 1965. Design and use of social accounting systems in state developing planning.

This study is concerned with the development of a comprehensive information system at the state and regional levels for private and public planning. A social accounting system was developed for the state of Iowa in the form of a 70-sector matrix to measure the real and financial transactions in connection with the production, consumption, accumulation and regional trading processes. The model includes detailed current and capital account transactions for industry, households, and government, and a system of classification converters that depict the functional relationships among the data to provide an integrated and comprehensive system of real and monetary flows for evaluation, analysis, and information production for planning purposes.

MICHAEL J. LAVELLE, Ph.D. Boston College 1966. The Soviet image of the United States economy: 1953-1963.

This study presents the Soviet image of American business cycle history, the U.S. growth record, and the American experience in the utilization of labor and capital. A secondary purpose has been to show changes that have taken place in the Soviet image in the past ten years. Beginning in 1958, the need felt by Soviet economists to have a measure of their own economy, led to fuller use of U.S. statistics and concern for factual comparisons between the U.S. and Soviet economies.

MALCOLM DOWLING, Ph.D. Pittsburgh 1965. An industry model of inflation.

CHARLES G. DRAKE, Ph.D. Missouri 1965. Unemployment insurance as an automatic stabilizer.

In an examination of contributions, benefits, total and taxable wage data for cyclical conformity the benefit series show consistently better cyclical conformity than the contribution series. Unemployment insurance is a reasonably satisfactory automatic stabilizer in terms of timing and direction of changes of values but has significant limitations in relative magnitude.

MICHAEL KERAN, Ph.D. Minnesota 1966. Monetary policy and the business cycle in Japan.

This study tests statistically, with the use of difference equations, the idea that if internal and external instability are consistent (e.g., internal inflation associated with external deficits), one policy tool can move the system simultaneously toward reducing external and internal fluctuations. This study shows if external imbalance is due to internal factors, a response mechanism operates with lags, monetary policy directed at reducing external instability will actually increase fluctuations, as in Japan's case. If policy is directed at reducing internal fluctuations would be reduced.

JOHN W. BAY, Ph.D. Boston College 1966. Time lapse and cyclical changes in commercial bank investment portfolios, 1949-1961.

In recent years there has been considerable controversy in the literature, both theoretical and empirical, over how commercial banks adjust their portfolios cyclically. The purpose of this dissertation is to examine the manner in which banks adjusted their portfolios cyclically from 1949 to 1961. Special emphasis is placed on the passage of time as a method of adjusting investment portfolios. The findings of the study show that the passage of time is an important part in bank adjustments during expansions and recessions. Changes in maturities of government securities due to the passage of time are an alternative to, or supplement to purchases and sales of securities.

BEN W. BOLCH, Ph.D. North Carolina 1966. A spectral analysis of interrelationships between the money stock and certain asset markets.

Spectral and correlation analysis are applied to several economic time series representing percentage rates of change in a measure of the money stock (currency plus demand deposits adjusted), a measure of commodity prices, a measure of production, a measure of equity prices, a measure of income velocity of money, and several distinct measures of yields on various types of interest-bearing assets. The period of the analysis extends from April 1955 to March 1965, and all series are sampled at semimonthly intervals. The aim of the study is to estimate leads, lags, and degrees of association between these series on both the time and frequency domains.

RICHARD L. BOLSTER, Ph.D. American 1966. The relationship of monetary policy to the stock market: the experience with margin requirements.

Margin requirements control entry into the stock market on a credit basis. In nearly all instances margin requirement increases have been followed by a halt in the build-up of security credit, a decrease in the rate of build-up, or a decline of security credit. Margin requirement reductions have been followed in nearly all cases by an increase in security credit.

a decrease in the rate of decline, or a halt in the decline. A similar trend in stock prices has usually followed somewhat later.

DAVID T. HULETT, Ph.D. Stanford 1966. A short-run model of commercial bank portfolio behavior.

The portfolio behavior of nine large New York City banks in the markets for securities and borrowed reserves was investigated within the framework of a three-week first difference model. Deposits and business loans are assumed to be exogenously determined; the banks predict portfolio stability from the composition of deposits. Stable deposits were allocated to long-term securities with a lag, large interest rate elasticities were found, and the banks adjusted rapidly to changes in their desired portfolios.

EDWARD A. K. KALIAN, Ph.D. Columbia 1966. Money and banking in Iraq, 1914-1918: a study in economic history.

RONALD A. KRIEGER, Ph.D. Wisconsin 1965. Inflation propagation in Argentina: a short-run dynamic analysis.

Propagating factors that perpetuate the process of inflation in Argentina are investigated through the formulation and solution of a dynamic open-economy model that features a free-market "rural" sector and an administered-price "urban" sector. Quantitative and institutional evidence demonstrate the relevance of the assumptions of the theory to Argentine reality for the period 1958-64. Tests performed on an econometric version of the model indicate a strong probability that the postulated linear relationships indeed exist.

EDWARD S. PEARSALL, Ph.D. Princeton 1966. An econometric study of financial markets.

This study investigates the applicability of functional models of supply and demand to the explanation of behavior in the vast network of financial markets in the real world. The flow-of-funds data of the Federal Reserve Board, covering 13 sectors of the economy and 17 financial market instruments, are used for a period from 1962 to 1964. Three models are distinguished; perfect competition, limited availability of credit (lender predomination), and forced loans (borrower predomination). The author specifies and estimates some 72 supply and demand equations.

GLORIA SEATTO, Ph.D. Rice 1966. Corporate demand for liquid financial assets, 1947-62.

The study focuses on postwar changes in the pattern of corporate holdings of liquid financial assets, factors which affect such holdings, and implications for policy which the findings suggest. The main hypothesis is that the relative decline in the corporate demand for money was caused by the growth in quantity and quality of money-substitutes, higher costs of money resulting from tighter monetary policy, expectations of increasing economic stability, the growth of trade credit, and managerial and technological developments within firms which resulted in more efficient utilization of money.

COLIN WRIGHT, Ph.D. Chicago 1966. Saving and the rate of interest: an empirical investigation.

The author derives a consumption function which includes wealth, expected income, and

the rate of interest by assuming that individuals act as though they maximized an n period utility function, containing current and future consumption as well as wealth, subject to a budget constraint containing the present value of present and future income. He argues that the coefficient of the interest variable is an estimate of the substitution effect and finds that it is significantly negative, which implies that the compensated saving elasticity is significantly positive.

JAMES A. ZWERNEMAN, Ph.D. Notre Dame 1966. Credit unions in Massachusetts: a financial analysis.

Public Finance; Fiscal Policy

JOHN R. ALLAN, Ph.D. Princeton 1965. The income tax burden on Canadian stockholders.

The author analyzes the difference between the burden on the corporate shareholder in Canada that is imposed by the present combination of corporate income tax and individual income tax, and the burden that would be imposed if partnership treatment were substituted. Computations are made for both distributed and retained earnings and for various assumptions regarding the shifting of the business tax. The results are examined for their effects upon progressivity.

RONALD DURANT, Ph.D. Wisconsin 1966. An analysis of the earnings dynamics of Wisconsin income taxpayers for the period 1948-1960.

It is the purpose of this thesis to investigate the dynamic aspect of the personal earnings distribution. The results include empirical estimates of the determinants of such measures of earnings change as (1) the absolute and (2) the percentage change in earnings during any one time-period. The vehicle for the analysis undertaken in this thesis was the hypothesizing and testing of a multivariate regression model which analyzed the general determinants of the earnings dynamics of married male head-of-household taxpayers in Wisconsin and in the active work force during the period 1948-1960.

DONALD L. ELICKSON, Ph.D. Wisconsin 1966. The history of land taxation theory.

The literature concerning economic rent and special land taxation is reviewed. The Physiocrats and the classical economists regarded rent of land as having qualities different from other forms of income. Their critics and successors emphasized similarities rather than differences, tending to blur the valid core in the older distinction that incomes from site values of land invited special taxation as the best example of a pure surplus, "unearned" by a specific contribution to society.

CHARLES E. MCLURE, JR., Ph.D. Princeton 1966. An analysis of regional tax incidences, with estimation of interstate incidence of state and local taxes.

This examines, on an analytical as well as empirical level, the incidence of taxes on an open economy, specifically the extent to which the burden of taxes imposed by one jurisdiction can be shifted elsewhere. It concludes that 20 to 25 per cent of the burden of taxes is exported, depending on whether one takes a short- or long-run view of the shifting process.

M. EUGENE MOYER, Ph.D. Wisconsin 1966. The validity of income distributions from a multi-year sample of Wisconsin income tax returns.

The thesis is a critique of a new source of data on the economic behavior of households, the Wisconsin Assets and Income Studies' sample of individuals who filed Wisconsin income tax returns during the years 1947-1959. The data are unique in that they allow an analyst to follow the economic behavior of an individual through time.

WALLACE E. OATES, Ph.D. Stanford 1965. The stabilization and tax harmonization problems.

The first part is a formal study of the stabilization problem in a federalist system with both central and subcentral government units. Using a model complete with financial-asset variables and portfolio-balance relationships, the analysis suggests that regional government bodies are likely to be severely constrained in their capacity to use conventional fiscal policy for stabilization purposes. The second part investigates tax harmonization problems between regions where there is interregional mobility of resources and consumer units.

AIYANNA RAMINENI, Ph.D. Minnesota 1966. Comparative analysis of the Kaldor Indian tax reforms and the Shoup Japanese tax reforms.

Both reports recommended (1) the inclusion of capital gains in income with a proviso that the top bracket rate should not exceed 45 per cent, and (2) an enlargement of the personal tax base through the introduction of a net-wealth tax, an integrated general gift tax, and a personal expenditures tax recommended by Kaldor only. However, the tax measures as enacted differed considerably when each country tried to modify the proposals to fit its national goals. The Indian measures, which were aimed at achieving socialistic goals, resulted in operational inefficiency and adverse economic effects. In contrast, the Japanese measures, which were aimed toward achieving capitalistic goals, were operationally successful and had favorable economic effects.

- MICHAEL K. TAUSSIG, Ph.D. Mass. Inst. Technology 1966. The charitable contributions deduction in the federal personal income tax.
- PETER A. TINSLEY, Ph.D. Princeton 1966. Potential GNP and discretionary fiscal policy. The author specifies and estimates a relatively disaggregated model of the U. S. economy after the war on the basis of quarterly data. Special emphasis is given to the influence of alternative tax policies and to an examination of existing notions of "capital output." For his own estimates, nonlinear production functions are used. Endogenous explanations of several types of expenditures for consumption and investment, as well as of employment, wages, and prices, are provided.

- E. RAY CANTERBURY, Ph.D. Washington (St. Louis) 1966. A dynamic theory of international short-term capital flows.
- This study develops a dynamic theory of foreign exchange, with emphasis on short-term capital flows. Its hypothesis is that traditional foreign exchange concepts are not necessarily applicable in determining appropriate international monetary policy. The concept of interest-rate parity is re-examined in the light of recent foreign-exchange market developments. The new model is presented in the form of difference equations. Novel aspects in theory are developed, and contrasted with those of the conventional covered interest-rate arbitrage function. *Spot* and *forward* price-determination equations are solved simultaneously for exchange prices and for a new "interest-rate parity." Perhaps the most interesting implication of the model is that a policy of pegging domestic short-term interest rates will, under certain circumstances, tend to affect the forward rate in a direction opposite to that desired.
- ROBERT P. CLARK, JR., Ph.D. Johns Hopkins 1966. The LAFTA debate in Venezuela: a test case in building consensus.
- The dissertation deals with the policy of the Venezuelan government towards the Latin American Free Trade Association and other forms of Latin American economic integration from 1958 to 1965. Of special interest is the treatment of business-interest group behavior regarding the issue, as well as efforts by government bureaucrats to build a consensus in favor of joining the Association.

THOMAS P. ENGER, Ph.D. Ohio State 1965. Protectionism and development.

The objective of this study is to determine whether unrestricted international trade contributes to economic development or serves as a barrier to retard development. First, a systematic examination is made of the theories and policy statements. Second, recent empirical studies on the relationship of international trade to economic development are analyzed to determine whether they support or refute points raised by dissenting economists and the United Nations. Lastly, three case studies of underdeveloped nations are analyzed. Peru, Burma, and Jamaica were selected on the basis of differences in economic structure. The analysis of each nation provides an opportunity to apply trade theory and to determine whether commercial policy has made any identifiable contribution to economic development.

MICHAEL GARDONE, Ph.D. Kentucky 1965. The international role of the dollar.

STEVEN M. GOLDMAN, Ph.D. Stanford 1966. Economic growth and international trade: a study in the theory of economic development.

The role of primary good exports in economic growth is examined within the context of a three-sector model of capital accumulation and a dynamic world market. The pattern of production and growth is then characterized with reference to the rates of growth in domestic population and world demand and under varying assumptions regarding capital intensities of the production sectors.

LOUIS G. GUADAGNOLI, Ph.D. American 1965. Role of medium-term export credit guarantees and insurance in financing economic development: Argentina as a case study.

The dissertation consists of two parts: the first considers the principles of operation of medium-term export credit guarantee and insurance programs. In the second part guaranteed medium-term export credits are evaluated as a source of financing for the developing countries and there is included a case study of Argentina's experience with such credits during the years 1960 to 1962.

HELMUT A. HAGEMANN, Ph.D. Harvard 1966. The supply and demand for international reserves.

KANJI HAITANI, Ph.D. Ohio State 1965. Japan's export trade: its structure and problems.

A comprehensive analysis is made of the problems arising from the structural changes in Japan's export trade primarily from 1953-1963. Japan's best chance to succeed in expanding its exports more rapidly, and thereby make possible a continued rapid growth of its economy, lies in its making constant and intensive efforts to: (1) improve the national competitiveness of its exports, especially of industrial machinery and passenger cars; (2) extend increasingly larger amounts of export credits at competitively low cost to underdeveloped countries; and (3) eliminate, through vigorous economic diplomacy, various restrictions imposed on Japanese exports.

KYUNG MO HUH, Ph.D. Michigan 1965. The development and prospects of Japan's trade in Asia.

ASHOK KAPOOR, Ph.D. North Carolina 1966. Foreign collaborations in India: problems and prospects.

The role of foreign collaboration is to a large measure determined by the factors preventing effective utilization of transferred rights and services (and capital). Changes in business and government policies could lead to a greater inflow and better utilization of foreign rights and services. This study attempts to determine some of the specific problems of interbusiness and government-business relationships and the changes in business and government policies that are needed in order to secure greater contribution for foreign rights and services.

ABDULHAY KAVOUMY, Ph.D. Washington 1965. Monopoly pricing of Afghan Karakul in international markets.

Karakul once was a virtual monopoly of Afghanistan. Its principal market is foreign. This study develops an estimating model based on standard trade theory and applies it to discover that Afghanistan reaped a small gain but lost a substantial share of its monopoly in world markets when it attempted to exploit its monopoly position. A good deal of the apparent gain was borne by domestic producers.

JAMES L. LEIBFRIED, Ph.D. Kansas State 1965. A study of the International Wheat Agreement: its development, negotiation, and provisions.

The author presents the view that the outcome of the debate in the United States concerning the role of the International Wheat Agreement may have far reaching effects not only because of the international economic and political prominence of the United States but also because of her major role in the international wheat trade and generally strong support in the past of international commodity agreements. The purpose of this case study was to make an objective contribution to the discussion and to offer some constructive suggestions. Following a review of relevant economic and political concepts, an attempt is made to answer nine relevant questions.

PETER V. MINI, Ph.D. Tulane 1965. Private long-term foreign investment in Italy, 1956-61: its causes and its contributions to Italy's economic growth.

During 1956-61 there was a ninefold increase in the annual flow of foreign private investment into Italy. The Organization for European Cooperation and Development liberalizations of capital movements and commodity trade, Italy's restrictive monetary policies, the rapid growth of its stock prices in 1959-61, and the Swiss situation of high liquidity are the most important causes of the capital inflow to Italy. Sectorally, this capital is attracted by Italy's export-oriented industries. Geographically, it is concentrated in the industrialized North. This unbalanced regional distribution runs against the postulates of the Vanoni Plan, but indirectly contributes to Southern development by encouraging labor "migration" to the North.

- JAMES W. VIGEN**, Ph.D. Ohio State 1965. Analysis of demand for wheat in the European Economic Community with projections to 1970 and 1975.

The wheat economy of the EEC is examined through construction of statistical demand relationships for total domestic demand, demand for wheat consumed as food, and demand for wheat utilized as livestock feed. Equations are developed for individual countries and fit to data for the period 1951-1962 by means of multiple regression technique. Projections made for the years 1970 and 1975 indicate declining per capita consumption of wheat as food and increased utilization of wheat as livestock feed.

DENIS W. WARE, Ph.D. Ohio State 1965. The economic implications of free trade in agricultural products between Canada and the United States.

The effect of tariff removal by Canada and the United States on 21 agricultural products is studied using least-squares multiple regression analysis. These products represent consumer items such as frozen vegetables and inputs such as corn. Estimates made for 1960 indicate that for the majority of the commodities there would have been less than a 5 per cent change in trade volume, with little impact on third countries.

JOSEPH T. WHITE, Ph.D. Boston College 1966. United States direct foreign investment and host nation income levels.

The hypothesis of this thesis is that direct investment by firms intending to sell output within the host nation is a function of the Gross National Product and that host nation. Correlation and regression results indicate that such a functional relation does exist for U.S. direct investment in the manufacturing, trade and petroleum refining sectors. There is no evidence of such a relationship in most extractive (export) industries or in public utilities. The results of this thesis also show that significant institutional changes can change the parameters of this function.

Business Finance; Investment and Security Markets; Insurance

MUZAFFER AHMAD, Ph.D. Chicago 1965. Demand for life insurance.

The purpose of this study is to examine the influence of income and certain other variables on the purchase of life insurance. The data for 1956 and for 1962 collected by Michigan Survey Center were used. Analytic methods are simple, two-stage, and three-stage least-squares analysis. Income elasticity is suggested to be at least unity. It contradicts certain earlier findings. Tax subsidy initially shows a significant influence, though no firm conclusions are drawn. Number of income receivers and dummy for the group with unstable incomes are found to have discernible influence.

GEOFFREY CHURCHILL, Ph.D. North Carolina 1966. Simulation tests of an intermittent scheduling heuristic model for large lot size.

The thesis examines heuristic models which will yield low cost production schedules for the large-lot intermittent production case. Inventories are also considered. System optimality is not a goal due to the combinatorial problem implied. A phenomenon given the name "interference queueing" appears, in which delays are interlocking and cumulative if operation times vary. This causes local decision rules to yield results markedly superior to the results of any schedule attempted.

WIGHT J. ZULAUF, Ph.D. Minnesota 1965. Accounting analysis and the ability to pay wages.

The term "(in)ability to pay" has not been effectively or uniformly defined in the literature but involves an estimation of economic consequences of a wage demand. The major specifications of ability to pay are (1) the entity, (2) the wage demand, (3) the nature of the standard of economic consequences, (4) the time period, and (5) the quantitative level of the standard of economic consequences. Accounting's contribution is related to determination of firm rates of return, one of the key economic consequences. Tools of accounting analysis available to supplement the rate of return include productivity, marginal, cash flow, and breakeven analyses.

ER G. BIESIOT, JR., D.B.A. Southern California 1966. Concentration and trends in the California petroleum industry.

Investigation of California's petroleum industry's structure and behavior, 1924-1964, shows immense industrial growth as number of companies decreased. The majors' share of market remained fairly constant. Behavior of this rigid oligopoly varies from competitive to monopolistic, with crude production more competitive than refining. Gasoline prices in constant dollars have continuously declined. The industry's future is dependent on smog eradication, development of competitive sources, import quotas, Connally Act amendment, lowering of depletion allowance, and shale oil production.

ER D. BLACKWELL, Ph.D. Northwestern 1966. Price levels of funerals: an analysis of the effects of entry regulation in a differentiated oligopoly.

ARLES P. BLITCH, Ph.D. North Carolina 1966. Product innovation and price dis-

The purpose of this empirical investigation of the price policy of the innovator of cellophane, E. I. du Pont de Nemours and Company, Incorporated, in the period 1924-1951, is to test the hypothesis that the innovator used a discriminatory price policy. Analysis of the data supports the hypothesis. Findings also suggest that price discrimination in association with high entry barriers severely limited competition. Policy conclusion suggests nondiscriminatory pricing in new product markets with substantial obstacles to entry.

WILLIAM D. CLARK, Ph.D. Arkansas 1966. An investigation into the causes of motor-carrier loss and damage claims.

PETER M. COSTELLO, Ph.D. Michigan State 1966. Patents in the antibiotic industry.

The thesis explores questions of price and product competition in the antibiotic segment of the ethical drug industry under the influence of product patents. The industry is examined for the early 1940's through 1960 in an attempt to delineate the effects of product patents on technical progress, pricing, and on the competitive behavior of firms.

CURTIS CRAMER, Ph.D. Maryland 1966. The economics of natural gas pipeline pricing.

Natural gas pipeline companies render various types of services to many different consumers. This variation of services raises the question whether or not cost-pricing is reflected in gas pipeline rates. Rate comparisons indicate significant industry uncertainty in an appropriate demand-commodity rate structure. The study of natural gas pipeline rates reveals that the rates are responsive to demand factors and do not appear to follow closely the rules governing marginal cost pricing.

WAGIE G. DAFASHY, Ph.D. Arkansas 1966. An analysis of the entity theory of business enterprise.

PAUL D. DOAK, Ph.D. Iowa State 1965. Resource utilization and productivity estimates in the food and kindred products industry.

The elasticities of substitution of capital for labor were estimated for the three- and four-digit industries in the food and kindred products industry. These estimates indicate that the elasticities are greater than zero but equal to or less than one. These elasticities are not different from one in many instances which indicates that the Cobb-Douglas function adequately describes the relationship between factor usage and output in terms of value added. In addition, estimates of technological advance indicate that this factor has been responsible for more than 50 per cent of the increased output per worker as opposed to increased use of capital per worker.

ANTHONY N. DOHERTY, Ph.D. Tulane 1965. An economic analysis of section 2F of the Robinson-Patman Act.

This study consists of a theoretical and empirical evaluation of the provisions establishing legal liability for the buyer under the Robinson-Patman Act. The primary objectives of the study are twofold: first, to bridge the gap in theoretical economics by adapting, extending and elaborating upon the theory of price discrimination so as to provide a more comprehensive theory pertaining to the buying side of the market; second, in the light of the theory presented, to ascertain the influence of the buyer-liability provisions of the Robinson-Patman Act on competition, vertical-price relationships and economic integration.

ALFRED S. EICHNER, Ph.D. Columbia 1966. The emergence of oligopoly: sugar refining as a case study.

BRUCE ERICKSON, Ph.D. Michigan State 1965. Price fixing under the Sherman Act: case studies in conspiracy.

Of all antitrust law violations price fixing is the most common. Yet economists' knowledge about the causes and consequences of price fixing is limited. This study summarizes the literature on conspiracy and examines two price-fixing agreements in detail. On the basis of the foregoing it attempts to answer such questions as: What are the prerequisites for conspiracy? What conditions allow conspiracy to continue? What are the characteristic patterns of conspiracy in terms of industrial structure, conduct, and performance?

WILLIAM H. KAVEN, Ph.D. Cornell 1966. The impact of private label ice cream on industry structure and conduct.

The rise of supermarket chains has led to the marketing of a manufacturer's output under both manufacturer's label and a private label at widely different prices only partially explicable by differences in quality. This gap is to be explained by conditions of monopolistic competition for the chains' annual contracts in the case of the latter. There are important economies of scale in production. Hence the large manufacturers are squeezed severely by the chains and are unable to press their own label products effectively in the market, while small local producers unable to handle large chain store contracts are being forced out.

HELEN KRAMER, Ph.D. Wisconsin 1965. The economic impact of the aerospace and electronics industries in the United States, 1950-1961.

A linear regression model is used to measure by States the relationship between personal income and employment in the principal defense industries. Two alternative hypotheses, that large-scale military spending has occurred at the expense of the standard of living, and that this spending has been an essential prop to the economy, are not supported by the data. A third hypothesis, that the impact has been significant in selected regions, is confirmed for eight States.

DENNIS C. MUELLER, Ph.D. Princeton 1966. The determinants of industrial research and development.

On the basis of an investigation of survey data of individual firms, the determinants of the composition and size of expenditure on research and development it is found that sales volume and diversification positively affect the R&D expenditures of a firm. However, taking dividends, advertising and capital expenditures as the other endogenous variables, and profits and depreciation as the major explanatory variables, the author finds a negative correlation between sales and research. He offers alternative explanations and policy suggestions on basis of divergent findings.

FRANCIS X. TANNIAN, Ph.D. Virginia 1965. Water and sewer supply decisions: a case study of the Washington Suburban Sanitary Commission.

This study analyzes particular local public-spending decisions, using the suburban Mary-

land region near Washington, D.C., as a case study area, with emphasis on the post-World War II period. An analysis of the role played by the Washington Suburban Sanitary Commission leads to the conclusion that the Commission's performance "has been undesirable because its supply decisions have been wasteful" and that the Commission's "institutional structure has induced misuse of public power by private initiative." The study calls for "more economically aware and responsive institutions . . ." to assure narrowly distributed political largesse is replaced with economic efficiency.

CHARLES L. TROZZO, Ph.D. Harvard 1966. Technical efficiency in the location of integrated blast furnace capacity.

ALEXANDER G. VICAS, Ph.D. Princeton 1966. The lag of unrestricted imitation following product innovation.

Presents case studies of eleven product innovations, not protected by patents, in three industries—cigarettes, fountain pens, and phonograph records. Various hypotheses on the lag of imitation behind innovation are tested with reference to data obtained chiefly from the daily press and trade journals.

MELVIN M. WAGNER, Ph.D. California (Berkeley) 1966. Interregional competition in the frozen vegetable industry.

Long-run transportation models incorporating estimates of regional production costs and consumption compared with past trends indicate continued cost (and price) reductions and resultant large increases in consumption in this competitive industry. Transport firm output is measured in units of weight at the point of consumption (distance a summary of bundles of inputs) instead of ton-miles. The correspondence between assumptions of transportation models and of theory relevant to the long run is emphasized.

JOHN A. WALGREEN, Ph.D. Boston College 1965. The economics of ocean liner freight conferences.

This dissertation is a study of the pricing of ocean liner freight carriage in United States foreign trade. Freight rates are determined by cartel-like associations of steamship lines known as shipping conferences. The economic factors which create and which limit the monopoly power of the conferences are analyzed. The author concludes that the operations of shipping conferences in U.S. foreign trade produces some economic misallocation of resources but that the exploitation of conference monopoly power is restricted by competition from nonconference shipping services, secret price cutting by conference members, and shippers' monopsony power.

JAMES E. WILLIS, Ph.D. Tulane 1965. A study of growth in the telephone industry of Louisiana from 1950 to 1962.

This dissertation is an investigation of a factor presumed to have influenced the diverse growth patterns of sub-state residence main telephone stations in Louisiana from 1950 to 1962. Previous studies indicated that station growth should have been related to changes in employment levels. Statistical analysis of the data, however, indicates that there is no consistent influence on the growth patterns attributable to employment level changes. Possible causes for these observations and suggestions for further study are offered.

Land Economics; Agricultural Economics; Economic Geography; Housing

WILLIS E. ANTHONY, Ph.D. Minnesota 1965. Size structure and growth of livestock slaughter firms.

HAROLD L. BAKER, Ph.D. California (Berkeley) 1966. Role of timber growing in land use in Hawaii.

The role of timber growing in land use in Hawaii is determined through the application of equilibrium economics. Projected long-run demand for Hawaiian-grown timber is derived in the goal year 2000. Next, the expected long-run timber supply function is developed, giving full cognizance to the timber demand-supply situation throughout the Pacific Basin. Finally, these functions are equated, and the timber volume thus established translated into the acreage needed for timber growing.

RICHARD C. BARTH, Ph.D. Wisconsin 1966. A study of the demand for housing.

MERRILL J. BATEMAN, Ph.D. Mass. Inst. Technology 1965. Cocoa in the Ghanaian economy.

KONRAD BIEDERMAN, Ph.D. Ohio State 1965. Regional loan rate differentials for wheat.

The study explores the feasibility of using a transportation model to determine optimum regional loan rate differentials for wheat. This approach assures independence from historical price relationships which may be distorted. It also permits use of lowest-cost mode of transportation and treatment of each class of wheat on the basis of its own supply and demand conditions. Findings indicate that this approach is a workable alternative to present methods of setting loan rate differentials.

FAHMI K. BISHAY, Ph.D. Iowa State 1965. Marginal rates of substitution between land, labor and fertilizer in relation to the optimum planning of resource combinations.

The object of this study is to investigate the economic and technical relationships between fertilizer (as a form of capital), land and labor. For this investigation to be carried out, the derivation of production functions which relate fertilizer, labor, and land have been conducted. These functions represent the production of nine crops, namely: corn, cotton, wheat, barley, cereals, rice, paddy, maize and peanuts raised in five countries: the United States, Canada, Sweden, U.A.R. (Egypt), and India. The determination of the optimum policies with respect to resource allocations in fertilizer investments versus other productive projects have been investigated. However, the approach is to modify the problem into agricultural policy formulation and to use programming techniques to determine the optimum solution. Moreover, some measures of reliabilities reflected in establishing the confidence intervals for marginal physical products, isoquants, and isoclines have been specified too.

BARRY W. BOBST, Ph.D. Washington State 1966. Optimal spatial and structural changes in Washington's fluid milk industry.

The number, size, and location of fluid milk plants in Washington in 1975 have been estimated. One estimate was made in an uncontrolled setting, in which fluid milk plants were allowed to become spatial monopsonists and monopolists in the raw and processed milk markets, respectively. Another estimate was made under a set of assumed restrictions which limited the share of the market that could be supplied by any one plant in each geographic consuming area.

LARRY M. BOONE, Ph.D. Washington State 1966. A study of dry edible pea prices in the Pacific Northwest.

A description of the market structure was developed from information obtained by interviews with people in the industry supplemented by published supply and disposition data. Price appears to be influenced primarily by domestic supplies and by foreign demand. Domestic disappearance and price do not appear significantly related.

PAUL G. BRADLEY, Ph.D. Mass. Inst. Technology 1966. The economics of crude petroleum production.

KEITH C. BROWN, Ph.D. Southern Methodist 1966. A theoretical and statistical study of decision-making under uncertainty: competitive bidding for offshore petroleum lands.

Bids for leases appear to be lognormally distributed with constant variance within scales. To make an optimal bid for a tract, it is necessary to estimate the probability that any proposed bid has of winning. The variance of the distribution of competitors' bids may be estimated from similar past sales and an iterative procedure is suggested for estimating the mean. The resulting formulations are subjected to sensitivity analysis and their implications discussed.

GEORGE L. CASLER, Ph.D. Purdue 1966. The effect of cardiovascular impairment on farm organization.

An analytical study of systems selection by obtaining the least-cost solution to a network and then comparing the effect of the systems selected on the potential profit of the farm using linear programming. The effect of restrictions appropriate for farmers with heart disease, reduced rates of energy expenditure and hours worked per day was estimated with different levels of mechanization.

CHAO-CHEN CHEN, Ph.D. Cornell 1965. An analysis of the supply-demand-price structure of onions in the United States.

R. GENE CONATSER, Ph.D. Southern Methodist 1966. Land reform and economic development: Mexico 1930-1960.

There exists a growing literature on the potential contribution of a program of land reform to the economic development of the less developed countries of the world. In the period from 1930 to 1960, Mexico pursued an active program of land expropriation and distribution which transferred almost 35 per cent of the total crop land of the country to groups of formerly landless peasants. An examination of the available data indicates that this land reform program did not result in increased agricultural investment, greater factor mobility in agriculture, or more efficient sized agricultural units. The major visible contribution of the program is reduced rural unrest.

RALPH W. CUMMINGS, JR., Ph.D. Michigan 1965. The structure and functioning of the Indian wheat market, with special reference to Khana, Punjab, 1956/57-1963/64.

RACHAEL DARDIS, Ph.D. Minnesota 1965. The welfare cost of agricultural protection.

A partial equilibrium model for both final and intermediate goods is developed to measure the welfare cost of agricultural protection. In the second part of the study absolute and relative costs of protection are obtained for the grain sector in the United Kingdom and the feed-livestock sector in West Germany for selected years. It is concluded that cost rather than degree of protection is important since it reflects the economic consequence of protection.

DINKERRAI R. DESAI, Ph.D. Kansas State 1966. The effect of selected weather factors on yields of wheat grown under various rotational practices at the Fort Hays Branch Agricultural Experiment Station.

In order to improve the information available to farmers for decisions with respect to abandonment of growing wheat prior to harvest, the effect of selected weather variables and cultural practices on wheat yields, for various portions of the growing season, was studied using regression analysis. Yield data for more than 30 years from experimental fields were used and compared with results obtained from geographically aggregated data by other researchers.

MOHAMED G. D. A. EL-DAHAB, Ph.D. Kansas State 1965. An aggregation procedure for deriving representative farms in estimating supply functions.

This study was designed to evaluate aggregation procedure for utilizing sample data for constructing representative farms to be used in estimating aggregate supply functions by linear programming procedures. Results obtained are compared with those of a previous study using unaggregated data for 49 sample farms. Producers' response to milk price changes is determined by programming nine constructed representative farms under three basic milk price situations programmed in the original study of 49 farms. The constructed representative farm method results in a reduction of 82 per cent in computational time and results obtained indicate that estimates by this method are not substantially different from those obtained by conventional programming procedures of the original study.

ABDEL EL-YAMANI, Ph.D. Minnesota 1965. The process of technological advance in Egyptian agriculture: lessons from the U.S. experience.

A. MYRICK FREEMAN, II, Ph.D. Washington 1965. The federal reclamation program and the distribution of income.

The Bureau of Reclamation, in developing irrigation projects, has significant effects on income distribution. This dissertation examines a sample of single purpose Bureau of Reclamation projects, using a theoretical model embodying both efficiency and redistribution elements, to determine the welfare effects of such projects. It is found that most of the Bureau projects examined, corrected for proper measurement concepts, were inefficient. While the redistribution effect was in the desired direction, any reasonable weights still yielded approximately the same ranking of projects, and did little to improve their overall efficiency rating.

PHILIP H. FRIEDLY, Ph.D. Southern California 1965. Requirements and determinants for the economic allocation of space in community planning.

HARALD B. GLAEVER, Ph.D. California (Berkeley) 1966. Optimal dairy cow replacement policies.

A Markovian dynamic programming framework is used for the formulation of a dairy

cow replacement model, in which different cow characteristics exhibit stochastic variation. A multi-variate normal model is used as a basis for estimation of cow population parameters from empirical data. The normal stochastic process is then transformed to a Markov process by definition of new state variables. Optimal replacement policies for dairy herds are derived under different price assumptions.

BERNAL L. GREEN, Ph.D. Purdue 1966. Factors affecting participation in selected outdoor recreation activities.

This study is one of several related endeavors designed to explore the possibilities for alternative uses of resources in low-income areas. Multiple regression techniques are used to analyze the extent that participation in four outdoor recreation activities (camping, boating, fishing, and hunting) is affected by selected independent variables. Data obtained by mail questionnaire indicated occupation, age, vacation time, education, type of equipment owned, income, marital status, and distance to recreation area as the significant variables.

JAMES W. GRUEBELE, Ph.D. Minnesota 1965. Changing market structure of the Minnesota dairy manufacturing industry.

WILLIAM O. HANCOCK, Ph.D. Purdue 1966. Farm plans and supply response estimates for Indiana: hog and beef cattle farms.

Objectives are to (a) derive farm plans and (b) estimate supply response of hogs and beef cattle production to prices in Indiana as part of a North-central regional study. Thirty-eight representative farm types based on size, location, and products are classified from a 971-farm survey. Representative farms are linear programmed for various price combinations for hogs, beef cattle, and corn. Normative supply responses for Indiana are estimated based on the numbers of farms in each category.

IAN W. HARDIE, Ph.D. California (Berkeley) 1966. Deriving implicit grower prices for a walnut processing and marketing cooperative.

How should the total pool of profits earned by a marketing cooperative be divided among its members? Finding an answer to this question for Diamond Walnut Growers, Inc. (a California cooperative) constitutes the objective of this dissertation. A linear programming model is formulated to maximize the cooperative's profit by optimally allocating approximately 270 types of unprocessed walnuts to the finished products. The dual solution of this linear program attaches shadow prices to the unprocessed walnuts.

ALBERT C. HEINLEIN, Ph.D. Western Reserve 1966. A probabilistic approach to evaluating community expenditures on industrial development.

The study explores the feasibility of using statistical decision theory to evaluate alternative community industrial development efforts. A 5-variable model is found to account for 90 per cent of the variance in number of new plants per community. Industrial parks make the greatest improvement in probability of attracting a new plant with an expected payoff of about 2:1.

GLENN A. HELMERS, Ph.D. Iowa (Ames) 1965. Factors affecting the demand for farm labor.

Demand functions for several types of farm labor are estimated nationally and regionally for the ten farm production regions. Least-squares time-series regression procedures are employed with independent variables representing a number of aspects of the farm and nonfarm economy. Migration functions for farm population, hired, family and total farm labor are estimated using a least-squares cross-sectional analysis. State data are employed through the use of differences in dependent and independent variables between selected years. The results indicate substantial structural differences in the estimated demand and migration functions between hired and family farm labor.

WILLIAM W. HICKS, Ph.D. Stanford 1965. The agricultural development of Mexico, 1940-1960, with special emphasis on cotton and wheat production in Northern Mexico.

I. Introduction: Structural change in Mexican economy. Changes in share of income and exports from agriculture and share of agricultural products in total imports. Changes in level and pattern of demand for agricultural production. II. Mexican agricultural output—increase in total agricultural output by crop, geographic distribution, "commercial" farming. III. Agricultural inputs in Mexican agriculture—harvested area, labor, irrigation,

fertilizer, machinery, improved seeds, pesticides and credit. IV. The productivity of inputs in Mexican agriculture, for the country as a whole and individual states. V. Evaluation of Mexican agricultural development—qualified definition of optimal strategy.

YU-CHU HSU, Ph.D. Cornell 1965. Income variability and resource productivity of rice farms in Changhwa and Nantou Counties, Taiwan, China.

GEORGE JOYCE, Ph.D. Alabama 1965. An analysis of the intra- and inter-market shopping travel behavior of motor vehicle users in a small community area—Gardendale, Alabama.

GERALD L. KARR, Ph.D. Southern Illinois 1966. Economic models of the feeder-swine market.

This study is concerned with the price-making forces of an intermediate good which is undergoing a rapid change in structure. Particular attention is given to the feeder pig pricing system. After developing theoretical models with different assumptions as to expectations, certain models are tested.

RICHARD T. F. KING, Ph.D. California (Berkeley) 1965. River basin projects and regional development: an examination of public investment criteria in the light of Mexican experience.

After a theoretical discussion of different approaches to evaluating large-scale public investment projects in underdeveloped countries, an examination of Mexican regional development problems and policies, and an analysis of the way in which river basin projects might stimulate regional economic development, several hypotheses are tested in the case of a sixteen-year-old Mexican project, the Tepalcatepec Project. As predicted by much development theory, agricultural development has been stimulated but not the intended industrialization.

JOHN A. KNECHEL, Ph.D. California (Berkeley) 1966. Dynamic analysis of capital management for California fluid milk producers.

Dynamic linear programming is applied to determine the optimum long-run (30-year) path of investment for a representative firm, given: the firm's initial resource organization; the relevant technical, institutional, and economic structures; and the relationship between the proprietary enterprise and the household. Neoclassical microeconomic analysis and capital management theory are critically appraised. Variations in the model analyze the sensitivity of capital growth to changes in technology, debt-equity structure, producer-distributor contractual arrangements, consumption behavior, time-discounting, and the objective criterion.

EMANUEL LANDAU, Ph.D. American 1966. The public control of air pollution—a case study in agriculture.

For developing effective air pollution control measures, estimates of benefit and costs are essential. The most manageable estimates of damages due to air pollution are estimates of damage to crops and livestock; at prices paid the farmer, this is currently estimated at \$500 million a year. Although these estimates of national crop damage are undoubtedly inexact, there is a distinct possibility that, because of the prevailing concentration on observable damage only, they may represent substantial understatements.

JIMMY L. MATTHEWS, Ph.D. California (Berkeley) 1966. Price determination and supply adjustment in the California and United States asparagus economy.

This study develops a dynamic recursive model of the asparagus economy to be used as a basis for prediction and projection of prices and quantities. The model considers a four-product outlet for the utilization of asparagus and four supply regions. Because of the simultaneity in the demand matrix, the model is partially recursive with simultaneous equation subsets. The basic use of the model is to investigate the probable implications of several alternative values of market variables which can be influenced either by the asparagus industry or other interest groups. Primary among these is the probable economic impact of terminating Public Law 78.

VERNON C. MCKEE, Ph.D. Iowa (Ames) 1966. Optimal land and water resource development—a linear programming application.

JOHN H. MERRIAM, Ph.D. Claremont 1966. The influence of property tax differentials on the location of economic activity.

Effective rates of property taxation vary substantially among areas in the United States. This dissertation explores the potential effects of property tax differentials upon the location of economic activity. Numerous researchers, using correlation analysis, have examined levels of business activity and tax burden and have concluded that no significant relationship exists between the two. The location decision, however, is based on much more than relative tax levels, and a partial equilibrium examination of taxes and industrial growth does little to identify the effect of property tax differentials in a general equilibrium world. The case studies attempt to separate the influence of a property tax differential in a real world situation.

STEPHEN D. MESSNER, D.B.A. Indiana 1966. The application of benefit-cost analysis to selected urban renewal projects in Indianapolis, Indiana.

ROBERT G. MUELLER, Ph.D. Washington State 1966. Economies of size and management alternatives of commercial cow-calf ranches in Washington.

A study of cost variations in beef production due to kind, size, and management of selected cow-calf ranching operations in Northcentral and Northeastern Washington. The major cost reductions due to size of cow-calf ranches in the areas studied are achieved when the ranch is of sufficient size to handle 150-200 brood cows. In general, multiple-enterprise ranch organizations have higher net incomes than single-enterprise cattle ranches, as do ranches using range improvement practices to increase stocking rates.

RICHARD T. NEWCOMB, Ph.D. Minnesota 1965. The impact of technical change on the iron ore industry of Minnesota: 1917-1963.

Where high rates of depletion characterize production, normal measures of technical change understate its impact. The study employs disaggregation, explicit depletion parameters and aggregate production functions to estimate in two stages these separate impacts. In mining, technical change increases total-input productivity .036 annually. Depletion, observable in beneficiation, reduces this to a negligible rate of .01 annually, and is solely responsible for the decline in the aggregate average product of labor after 1940.

DONALD R. NICHOLSON, Ph.D. Cornell 1965. Milk supplies in relation to federal milk marketing orders.

DAVID W. NORMAN, Ph.D. Oregon State 1965. Natural resource characteristics as related to the pattern of agricultural income in certain specified areas of the United States.

The main objective of the study is an attempt to obtain a general exploration for the geographical pattern of agricultural income. This was undertaken in the belief that certain

possible determinants of agricultural income, specifically those related to natural resource characteristics, have not been satisfactorily considered in investigations up to the present time. Consequently, various determinants which other researchers have found important e.g., location, education, age, etc., were combined in one model, together with a number of variables designed to measure various characteristics of natural resources.

WILLIS PETERSON, Ph.D. Chicago 1966. Returns to poultry research in the United States.

The aim of this study is to identify downward shifts in the long-run farm supply schedule of poultry products arising from the use of new, more efficient inputs which have been created by poultry research (public and private) and to obtain a measure of the consequent saving in resources to society. The results indicate that on the average each dollar invested in poultry research in the United States since 1915 returns about 20 cents per year beginning at the date of investment and extending on into perpetuity.

EARL W. PHILLIPS, Ph.D. Colorado 1965. Income distribution as a factor in regional growth; with special reference to the Southeast United States.

YAKIR PLESSNER, Ph.D. Iowa (Ames) 1965. Quadratic programming competitive equilibrium models for the United States agricultural sector.

The dissertation consists of three parts: (1) an outline of a policy choice procedure with particular emphasis on the United States farm problem; (2) a development of a series of quadratic programming models whose solutions, if they exist, are partial or general competitive equilibria; and (3) an application of one of the models to the United States grain economy and a description of how the prescribed choice procedure can be carried out by solving an array of quadratic and linear programming problems.

MICHAEL V. E. RULISON, Ph.D. California (Berkeley) 1966. Agriculture resource adjustment and farm labor force decline, 1950 to 1959: a comparative interregional study.

This study deals with changes in the structure of the agricultural sector accompanying declining labor input during 1950-1959 in five U.S. economic regions containing nearly three-fourths of the farms and farm labor force. The most significant finding is the substantial reduction in differences between regions with regard to the structure of their agricultural sectors as indicated, for example, by the narrowing of the range of gross sales of farm products per farm.

M. T. R. SARMA, Ph.D. Chicago 1966. An analysis of factors influencing increases in rice yields within Japan.

This dissertation deals with the derivation of estimates of the effects of some factors which are generally considered to be of importance in bringing about the rapid increases of rice yields in Japan during 1949-61.

RUSSELL C. YOUMANS, Ph.D. Purdue 1966. An empirical study of underemployed agricultural labor in selected areas of Minas Gerais, Brazil.

This study is an attempt to identify the extent of underemployed agricultural labor on commercial farms in five locations in the State of Minas Gerais, Brazil. Marginal productivities were computed from Cobb-Douglas functions for the various resources and used in evaluating the efficiency of labor use with respect to immediate wages and with respect to alternative employments in both the farm and nonfarm sector.

ABDEL ZAKI, Ph.D. Ohio State 1965. Economic development in the U.A.R. (Egypt) and the role of the agricultural sector.

The study examines the necessary environment for economic development and the contribution the agricultural industries make to economic development in a developing economy. Special attention is given to the Egyptian economy. It is concluded that for economic development to take place political, social, and economic changes should take place simultaneously to provide new ideology which would permit change in the behavior and attitudes of citizens in the country. Such changes have occurred in Egypt. In this country investments have increased but they have been more rapid in the industrial sector than in the agricultural sector. Credit facilities need to be expanded and the rate of mechanization should be such that it replaces only those human resources which are taken from the farm sector of the economy.

CHARLES F. FLOYD, Ph.D. North Carolina 1966. Public policy for depressed areas with special reference to North Carolina.

The dissertation seeks to identify areas of localized depression in North Carolina, to analyze the reasons for such depression, to describe existing public programs that attempt to alleviate such problems, and to make policy recommendations. Attention focuses on two broad types of programs: efforts to move jobs to workers, and efforts to enhance labor mobility. Although both have merit and may be pursued concurrently, the mobility approach is considered to be the more promising.

WILLIAM S. PEIRCE, Ph.D. Princeton 1966. Selective manpower policies and the trade-off between rising prices and unemployment.

Describes and analyzes particular labor markets (factory, office, craft workers, etc.) and shows how selective manpower policies affect prices and unemployment. These policies include government personnel policies and programs for training, mobility, and labor market information. The study includes a discussion of the institutional factors that impede successful application of selective manpower policies in many areas. "Success" is defined as their effectiveness in reducing increases in wages and prices.

MARTIN M. PERLINE, Ph.D. Ohio State 1965. A comparative analysis of the trade union press.

The primary purpose of this study is to determine whether the nature and scope of trade union publications have changed over the past quarter century. These publications are also studies to glean information as to whether the trade union movement, as suggested by many critics, has lost its zeal for social reform. Eleven trade union publications were used in the analysis—drawn from the years 1938-1939 and 1960-1961.

ANDREW J. PETRO, Ph.D. Michigan State 1965. Employment shifts and city size—Michigan and Indiana 1950-63.

The economic activity of a city participates as a unit in the national economy, and can gain or lose employment or gain at a slower rate. A shift technique is used to measure the relative changes. The selected cities in Michigan realized a favorable employment shift; Indiana's were unfavorable. The analysis indicates that the employment shifts and population were uncorrelated and that industry composition had little impact on the shifts. The source of the shifts is the locational advantages and the shifts occurred primarily in the manufacturing sector.

BRIAN QUINN, Ph.D. Cornell 1966. Some problems of producing a labor force in Africa.

The dissertation is an attempt, using interdisciplinary analysis, to explain the low level of labor commitment observed in several African countries south of the Sahara. The thesis explores the hypothesis that this problem is a manifestation of a broader social phenomenon—the impact of industrialization on the structure of preindustrial societies. Drawing upon recent theoretical literature in the fields of sociology, anthropology, and psychology, a close relationship is postulated between the structure of preindustrial African societies and the mental and emotional stability of the individual. Industrialization results in social disintegration and personality disorder, including poor performance in the work places. Statistical evidence is presented from countries in West, Central and East Africa relating industrialization with various indices of social disintegration and available evidence of increased mental disorders.

ECONOMIC-DEMOGRAPHIC INTERACTIONS AND LONG SWINGS IN ECONOMIC GROWTH

By RICHARD A. EASTERLIN*

The slackened growth rate of the economy in the cycles of 1953-57 and 1957-60 has stimulated increased interest in the hypothesis of long swings in economic growth or "Kuznets cycles"—fluctuations which, in the past, have typically extended over periods ranging from 15 to 25 years. Several writers have pointed out similarities between recent experience and earlier lapses from full employment growth.¹ Others, however, have taken sharp issue with such views [9, 27, 54]. And two recent methodological analyses have reached agnostic conclusions about the validity of the long-swings concept [6, 10].

The main support for the concept so far has been empirical in nature. A number of scholars working with processed and unprocessed time series relating to various economic magnitudes have been struck by substantial swings in the data.² Quite a few remarked on such swings well before there was any explicit formulation of the concept itself. A variety of countries are represented in this work—among them, the United States, Great Britain, France, Sweden, Germany, Japan, Australia, and Canada, as well as some underdeveloped countries [8]. But the gnawing question of "why" the swings has received much less study. The reason for this is apparent: satisfactory theoret-

*The author is professor of economics, University of Pennsylvania, and member of the research staff, National Bureau of Economic Research. This paper is part of a NBER study, conceived within the framework of a broader inquiry being conducted by Moses Abramovitz, and has not undergone the regular NBER review procedures. The project has been supported in part by a contract with the U.S. Department of Labor, Office of Manpower, Automation, and Training. The comments of Abramovitz and the referee of this *Review* are especially acknowledged. Helpful observations at various points in the preparation of the paper were also made by, among others, Gary S. Becker, Arthur I. Bloomfield, Irwin Friend, F. Thomas Juster, Irving B. Kravis, Robert E. Lipsey, Jacob Mincer, Marc L. Nerlove, Almarin Phillips, Sidney Weintraub, Maurice Wilkinson, and participants in the Purdue University Seminar on the Use of Economic Theory and Statistics in Economic History. The paper has benefitted from the excellent assistance of Chantal de Molliens Dubrin. The charts were drawn by H. Irving Forman.

² For bibliography see [2-4, 22, 68] as well as that contained herein.

ical analysis has had to wait for fuller evidence on the nature of the swings themselves. And as such evidence has accumulated, repetitive patterns have come to light and certain theoretical suggestions have been advanced regarding the mechanism of the swings, most notably in the works of Abramovitz, Hickman, and Kuznets [2, 36, 41].

The purpose of the present paper is to develop more fully one of these possible mechanisms and to consider its relevance to past, present, and prospective experience. The mechanism centers on interactions between economic and demographic phenomena.³ The fact that demographic series frequently show pronounced longer term fluctuations suggests that this may be a particularly auspicious area for inquiry. Moreover, demographic variables are largely or wholly omitted from extant theoretical models of economic fluctuations. Before dismissing long swings as a statistical illusion, the model-builder might check the efficacy of his arsenal for the explanation of the observed waves of population growth, which, *ex post*, have been widely recognized as relevant to economic experience.

The next section offers some brief comments on the nature of the empirical evidence relating to long swings and summarizes some of the principal characteristics which have been observed. The analytical model of economic-demographic relations is then developed, followed by discussion of its relevance to actual and prospective experience. The discussion is throughout unfinished, in keeping both with the state of current knowledge and the intent of the paper. Whether long swings exist as an independent phenomenon is uncertain. The present writer has found the concept to provide a useful framework for analysis [20], and certain theoretical and empirical considerations militate in its favor. The aim of this paper is to note some of these considerations and thereby to contribute to further thinking and research.

I. Some Observations on the Evidence

Statistical Method. If one studies *unprocessed* annual data for incontrovertible evidence of long swings in all economic time series, he will not find it. In particular, most output series, in which processes of inventory change play an important role, exhibit such high annual variability that the longer term movement, if it exists, is far from obvious. On the other hand, there are series that move only sluggishly from year to year, but show pronounced longer term fluctuations. Some of these are illustrated in Figure 1. While one would not immediately

³ Recent papers by J. Parry Lewis and Manuel Gottlieb overlap the scope of the present paper [33, 50]. A major study by Lewis centering on the building cycle provides a detailed examination of British experience [49]. I am grateful to Professor Lewis for the opportunity of seeing a pre-publication copy.

FIGURE 1. OUTPUT, INCORPORATIONS, RESIDENTIAL CONSTRUCTION, IMMIGRATION, AND NET CAPITAL IMPORTS, ANNUALLY, 1820-1964

Legend:

1. Index of industrial and commercial production, 1899 weights (Frickey).
2. Gross national product, billions of 1954 dollars (Commerce).
3. Aggregate index of incorporations (Evans).
4. Number of incorporations (Dun and Bradstreet).
5. Production of nonfarm housekeeping dwelling units (Gottlieb).
6. Number of nonfarm dwelling units started (Blank).
7. Gross alien immigration per thousand total population per year.
8. Net alien immigration per thousand total population per year.
9. Net capital imports, millions of current dollars.

identify long swings in the aggregate output series plotted there, such movements are manifest in the other series, particularly in the period before World War I, and show similar though not identical timing. These other series—residential construction, incorporations, immigration, and capital imports—derive from quite different statistical sources; hence the likelihood of a common bias in the estimation of the series is small.

At this point one may plausibly ask: if one processes the data so as to reduce short term variability, do the longer term movements evident in the raw data for some series appear in others as well? The answer to this question is yes, the movements appear in a number of other series, though not all. The routes by which this answer is reached are almost as numerous as the investigators, each one of whom would doubtless have been grateful if supplied with a foolproof statistical technique for processing the data. However, while the different methods of statistical smoothing tend to result in a common answer to the basic question, they yield somewhat different conclusions on more demanding questions such as those of frequency, timing, and amplitude. Hence differences in method affect one's conclusions, and there is at the present time no widely accepted catalogue of long swing measures comparable to those of the NBER for the regular business cycle.

Moreover, for the period since 1914, statistical analysis of time series for evidence of long swings meets with an additional complication. The immense expansion and subsequent contraction of government expenditure associated with the two World Wars resulted in a major departure from the historical long-swing pattern.⁴ A central feature of this pattern, one reason for which is suggested in Part II, was concurrent swings in the growth rates of GNP and aggregate construction. However, the two wars, with their attendant restrictions on construction, forced a break in the pattern, with GNP moving in positive conformity to the expansion and subsequent contraction of government expenditure, and construction in inverse conformity. The result is to interject an additional fluctuation in the usual long-swing relation, differing in timing between the two series, as illustrated by the broken line in idealized fashion on the following page.

This additional fluctuation appears, of course, not only in these two series, but in others as well. It is only eliminated by a statistical procedure which averages together the intervals both of expansion and contraction of government expenditure, such as Kuznets' decade averages, perhaps the most severely criticized method.⁵

⁴ It is possible that the Civil War is another case of this sort, but the data at present are not sufficiently complete to determine this.

⁵ This paragraph perhaps meets the question raised by several discussants of Hickman's

One implication of these observations is that the issue of the "reality" of long swings is unlikely to be resolved, pro or con, by purely statistical studies, valuable and necessary though these are. To the extent one concentrates on output series relating primarily to the war-torn twentieth century, as has been true of the studies reaching agnostic conclusions, the more one is likely to be unconvinced. On the other hand, by emphasizing periods less disturbed by war and series in which the swings are prominent in unprocessed data, one may build a stronger case, though this inevitably leaves in doubt the question of current relevance. In any case, it is clear that statistical analysis needs to be complemented by economic analysis: are the observations on long swings consistent with a model of relationships based on economic theory? It is to the solution of this question that the present paper seeks to contribute.

If this point be granted, some tolerance on the side of methodology is perhaps warranted for the analyst of long swings. He is trying to piece together evidence on the nature and causes of a phenomenon, the presumptive duration of which lies in the neighborhood of two decades; observations on four or five swings therefore require series span-

paper [19, 27, 31], namely, whether experience since the 1930's is to be interpreted as one long swing or two shorter swings. The additional fluctuation is directly due to the movement in government spending (cf. [36, p. 493]), and is thus an interruption in the basic long swing.

ning a period of some 80 to 100 years. To secure observations for periods undisturbed by major wars the investigator is forced still further back into the nineteenth century. There are few continuous annual series spanning such a long stretch of years. If severe criteria of reliability are applied, perhaps there are none. In his effort to piece out the pattern, the investigator falls back on observations for some variables at more intermittent intervals, quinquennial or even decennial, which are to be used jointly with annual series for others. Under these circumstances, doctrinaire insistence on one technique or another seems idle; inevitably a fair amount of individual judgment is required, judgment influenced, among other things, by considerations of the reliability of the data and the desire to exploit the fragmentary evidence as fully as possible. Such considerations are often evaluated best by the individual closest to the data.⁶ This is not to say that anything goes; undoubtedly improvements can and should be made in statistical procedures, and research along these lines is helpful to the long-swings analyst.⁷

Characteristics of Long Swings. Despite difficulties of the type just described, growing evidence points tentatively to certain repetitive features of Kuznets cycles. Those particularly relevant to the present inquiry may be briefly enumerated, bearing in mind that the evidence is not always as complete as one might desire and relates chiefly to U.S. experience.

1. A swing in the growth rate of nonagricultural output, and, as it comes to be dominated by nonagricultural activity, GNP, tends to be followed with a lag by a swing in additions to the stock of both capital and labor.

2. It is accompanied by a swing in the rate of change of the unemployment rate (inverted), and correspondingly lagged by a swing in the *level* of the unemployment rate [2, 3, 36].

3. A swing in the growth rate of construction tends to coincide with that of nonagricultural output; the level of construction correspondingly lags [1-3, 36].

4. Swings typically occur also in the growth of output and inputs in manufacturing, mining, public utilities, and a number of service sectors, but not in agriculture (except in the case of areas undergoing new settlement) and government. Within the sectors exhibiting Kuznets cycles, a tendency is apparent for industries more dependent on busi-

⁶ To illustrate, Kuznets' use of overlapping decade averages arose from his reluctance to depart far from the decennial census which provided the benchmarks for the 19th century output estimates.

⁷ Research along these lines is currently being conducted by Michio Hatanaka and E. Philip Howrey in connection with the Econometric Research Program, Princeton University.

ness investment demand to lead those more tied to household consumption and investment demand [22].

5. Although farm output does not usually show long swings, there is a tendency for farm prices and income to do so [14, 22, 55].

6. Spatially, swings in the nonfarm sector are widely diffused among the various geographic divisions of the country. They characteristically take the form of an urban development boom. However, any single urban area does not necessarily participate in every swing [22].

7. The swings have typically been characterized by waves of immigration and internal migration [21, 24, 61-66].

II. *The Analytical Model*

Although the intellectual progenitors of the model suggested here are as numerous as the references cited in this and other papers by the present writer, particular acknowledgement is due to contributions by Kuznets [41-45], Abramovitz [2-4], Isard [37, 38], and Burnham Campbell [15, 16]. The model proceeds in three steps: (1) the impact of aggregate demand on labor-market conditions, (2) the effect of labor-market conditions on the number and spending behavior of households, and (3) the reaction of the latter on aggregate demand.

Aggregate Demand and the Labor Market. Assume, to start with, that growth of GNP in the last business cycle or two occurred at less than the full employment growth rate and that the economy has accumulated excess capacity with regard to labor. One manifestation of this would be a tendency toward a rising unemployment rate at successive business cycle peaks (or troughs). Assume, next, that for some reason the rate of growth of private investment rises, producing a corresponding upsurge in the growth of aggregate demand, and that the higher level is sustained for some time. The spatial distribution of this increased demand and the employment opportunities created thereby would not necessarily conform to that of the existing labor supply. On the contrary, in a developing economy the locus of investment opportunities tends to be predominantly nonfarm, whereas the increase of the labor force through natural growth of the working age population is disproportionately farm.

The increased growth in aggregate product demand would have a corresponding effect on the demand for labor in the centers of economic activity favorably affected. Initially, one would expect the increased labor input requirements thereby created to be met locally through an appropriate movement in the rate of change of the unemployment rate, and perhaps via a rise in the growth rate of hours. Increasing tightness of the labor market would tend to be reflected too in an increase in the rate of change of wage rates. The longer this process continues, the

more likely it becomes that labor force growth in the favored areas can be enhanced by migration in response to the new employment opportunities. The origins of the migration would be lower wage areas where in the country (notably the older farm areas) and/or where labor force growth might also be raised by an increase in labor participation rates of reserve labor groups such as females, young, and older persons. The relative role of the several possible sources of increased labor input in satisfying the new demand would depend on the supply elasticities of the groups involved.

Reaction on Household Growth in Centers of Increased Labor Demand

To the extent that increased labor input requirements are met by changes in employment or hours changes, one would usually expect the reaction to be provided to household growth to be relatively mild, since the beneficiaries of the increased flow of income are most likely members of established households in the area. To be sure, the high unemployment rate in the immediately preceding cycle(s) and the frequently higher average unemployment rate, may have led to a deferring of marriage by young persons or, for those already married and living with their parents, postponing the establishment of a new household. For these, the progressive improvement of labor market conditions would lead to implementation of decisions previously deferred. The longer the previous period of slack the more sizeable the quantitative effect of this would probably be. Moreover, if the market impact were for some reason particularly favorable to those in the household-forming ages, plans might be advanced for household growth accelerated through a general reduction in the minimum age of marriage and of household formation.

Typically, however, one would expect a more immediate and noticeable reaction on household growth in the centers of increased labor demand if the increased labor input requirements were met via migration. In this case the growth in persons employed is more nearly matched by a corresponding growth in the number of households. This is the significance of the migration response: in contrast to other sources of increased labor input it carries a much more sizeable implication for household growth in the areas of increased labor demand.

Reaction of Household Growth on Aggregate Spending. Households newly established in an area generate demands, not only for housing but for urban services generally as well as for the furnishing of the home. They thereby tend to create an urban development boom in residential construction, new municipal investment in services associated therewith, and new business investment in retailing and service activities. (The mechanism might of course involve an intermediate stage in which new migrants displace previous residents in established areas.)

areas and the latter are those immediately involved in new real estate development.) Thus the rise in households, typically associated with the migration flow, leads to further growth not only in consumer spending but in private and public investment as well, and it is this induced rise in the growth of aggregate demand which tends to sustain and prolong the expansion.

Why Kuznets Cycles Rather Than Business Cycles? There would be a multiplier effect on consumer spending, and possibly new business investment induced thereby, arising from already established households whose head or other members may have benefited from the new employment and income opportunities. A reaction of this type is standard equipment in theorizing about the regular business cycle. Why should the present chain of events, operating through household growth, result in a more protracted boom?⁸

One possible answer is based on the composition of the induced demand when household growth intervenes between the labor-market response and increased spending flowing therefrom. This view would emphasize the central importance of housing and real estate development and the associated stimulus to local government spending on municipal services and to business spending on retail services, many of which require a long gestation period to bring to fulfillment. This argument rests at bottom on special characteristics of the industries benefiting from the induced demand—on product supply conditions.

A second, and perhaps more compelling answer, is based on demand considerations. Marriage, household formation, and migration are critical decision points in the life cycle of an individual. Typically, they involve commitment to new and higher spending behavior over several years as a new home is established and a family started or settled, a commitment reflected in the substantial indebtedness to relatives and financial institutions typically incurred during this period of the life cycle.⁹ On this basis, one might reason that in a population that experiences a substantial rise in the growth of households there will occur not only a shift in the composition of consumption but a rise in the propensity to consume as well. This would be sustained over several years, carrying over from one business cycle to the next, and would become exhausted only gradually. In effect, such long term spending commitments are geared to a notion of permanent income, and tend to be rather insensitive to short term income changes.

It is this feature of longer term spending commitments which may

⁸ Charles Tiebout [67] has drawn a similar distinction between a long-run and short-run multiplier, with population growth playing a central role in the former.

⁹ The most thorough study I have encountered of spending behavior in relation to life cycle stage (which is not synonymous with age) is that by Lansing and Morgan [46], though even in this the stages are very broad. Consumer panel studies should generate still more pertinent data. Ferber's article [28] provides a valuable survey.

constitute the analytical key to Kuznets cycle phenomena. The frequent association of such commitments with series most noticeably marked by long swings has been pointed out particularly by Abramovitz. Because the feature has so far received insufficient attention, his statement merits repetition in full:

One common attribute of all these processes of resource development involving the movement of people from country to country and place to place, the formation of households and the birth of children, the foundations of business, and the investment of capital in highly durable forms is that they involve long-term decisions and commitments. Hence they pick up speed and come to fruition slowly and when they slow down, they are not easily or quickly set in motion again. They give rise, therefore, to long waves of resource development and output growth. These processes involving long-term decisions, on the other hand, respond only sluggishly to the impact of the ordinary short and mild business contractions. By contrast, the most prominent feature of short business cycles is a fluctuation in shorter term investment, particularly inventory investment [3, p. 414].

While the present concern is with household behavior, it is worth underscoring Abramovitz's point that various types of private business investment also involve longer term commitments. Perhaps the most notable of these arise in connection with the establishment of new businesses, a phenomenon which, judging from the long term series on new incorporations (Figure 1) exhibits long swings in the unprocessed annual data.¹⁰ (With regard to the future, the growth in importance as spending units of various government bodies and private nonprofit institutions, both potentially significant sources of long term commitments, suggests the need for study of them as well.) This line of reasoning obviously leads to the general view that *Kuznets cycles may arise from mechanisms, such as that under discussion here, which result in a bunching of long term spending commitments.*¹¹

The Effect of Major Wars on Kuznets Cycles. The analytical model sketched above starts with a private investment boom, but any source of sustained increase in the growth of aggregate demand could initiate the process, including government expenditure. In the case of major wars, however, the process is interrupted, because the war itself places constraints on new household formation and construction. At the same

¹⁰ Research on investment spending by new firms (or, more generally, in relation to the "life cycle" of business units) is scarce. One valuable study is that by Bridge [13]; cf. also [25, 70].

¹¹ A discussion of spending behavior inevitably leads to the question of financing, and thus to the role of monetary and financial variables in long swings. While this subject is clearly "off-bounds," it may be noted that money supply, interest rates, prices, capital imports (Figure 1), and similar variables do show long swings [cf. 2, 18, 41, 49, 68].

time, a protracted war sets the stage for a postwar Kuznets cycle boom, by building up substantial backlog situations not only with regard to private and public investment, but household formation and consumer spending as well. Thus, a major war would tend, on the one hand, to interpose an additional fluctuation during which the growth of GNP and aggregate construction pursue divergent paths, and, on the other, if one smooths this fluctuation statistically, to yield a Kuznets cycle movement of more extended duration.

Are Kuznets Cycles Self-Generating? While the interaction between economic and demographic phenomena emphasized here is chiefly of a multiplier type, there are clearly elements of induced investment on the basis of which one might postulate a self-generating model of the multiplier-accelerator variety. Also, the positive association between labor market tightness and growth of aggregate demand implies the possibility of labor cost changes which may react on investment spending in an adverse manner, tending to reverse the movement. On the other hand, irregular events such as wars, legislative acts (e.g., regarding immigration and wages), and speculative capital movements have affected observed long swings. The relative weight of endogenous versus exogenous factors in initiating the swings is in my view an open question requiring further research.

But the value of the present model does not hinge on resolution of the self-generating issue. As Irma Adelman [5] and others have shown, the Klein-Goldberger model of the regular business cycle is so highly damped that it requires stochastic shocks to produce oscillations of the business cycle variety. The principal value of that model lies in suggesting mechanisms which tend to produce oscillatory movements in response to such shocks. Similarly, while the present analytical scheme leaves open the question whether Kuznets cycles may be wholly self-generating or require either small or strong shocks, it does suggest a mechanism that tends to produce cumulative upward or downward movements over periods longer than the ordinary business cycle.¹²

Long Swings and Secular Growth. How, if at all, are Kuznets cycles related to the primary trend? Is the primary trend itself merely the path traced out by averages of successive Kuznets cycles? The answer suggested here is no. The primary trend reflects processes of technological change and of human resource and institutional development

¹² Clearly, the present analysis does not agree with the view proposed in a subsequent paper [7] by Mrs. Adelman that a shocked Klein-Goldberger *business cycle* model may be sufficient to account for observed long swings. In this connection, it is worth noting that the simulated long swings that she obtained were of smaller amplitude than those actually observed, and that the Klein-Goldberger model does not incorporate economic-demographic interactions of the type described here.

which lie outside the long-swing mechanism itself. However, in an economy where the free market system plays an important role in resource allocation, the pace at which new technology is adopted and diffused tends to be modified by a Kuznets cycle mechanism. This is because efficient use of the new techniques flowing from the Industrial Revolution and its sequel has required increased geographic concentration of productive resources. This has created an imbalance between the geographic distribution of the growth of labor demand, arising from the industrialization process, and that of labor supply, which typically reflects the widespread population dispersion characteristic of an agricultural society. Successful adoption of modern industrial technology has required, therefore, redistribution of the population in conformity with the needs of the new technological basis of production, and the provision of the requisite goods and services for this relocated population. The induced stage of the Kuznets cycle mechanism, an urban development boom, is essentially the accomplishment of this requirement in a free market economy by a multiplier-type process.¹⁸

By way of contrast, this formulation may be compared with Isard's [37, 38; see also 58]. He sees the swings as arising from successive transport innovations, and the urbanization facet as a consequence of the impact of such innovations on the location of economic activity. The present view rests basically on the geographic imbalance between labor demands and supplies created by modern technology generally, and does not require a new transport innovation either to initiate the swing or to account for urbanization, though such innovations may, of course, play a part in particular times and places.

An implication of the present view is that various characteristics of long swings tend to change secularly. The growth opportunities constituting the focus of investment at an early stage of development will differ from those at a later stage; hence variations will tend to occur through time in the industrial characteristics and geographical distribution of the swing. For example, agricultural settlement or exports might loom large among the investment opportunities in the early growth stages; at a later time, domestic manufacturing may predominate. Similarly the potential sources of labor supply tend to change secularly. Immigrants may move more readily from one country at one time; from another, at a different time. The reservoir afforded by the farm population in older agricultural areas grows to a point but eventually begins to be depleted, and is perhaps increasingly replaced by

¹⁸The above aims to identify those conditions which characteristically underlie the observed association between modern economic growth and population redistribution. In certain cases, of which the United States is one, modern economic growth may, in addition, involve the opening up and settlement of new territory, and thus a further stimulus to population redistribution.

some of the nonfarm centers gradually being bypassed in the development process. Secular growth in family income and the appearance of innovations such as the automobile will alter the composition of induced household consumption expenditure—recent suburban versus earlier urban residential development is an illustration.

The analytical scheme suggested here bears a surface resemblance to Schumpeter's [57], for it implies that growth in a free market economy tends to proceed in irregular surges. However, the duration of the movement differs from any contemplated by Schumpeter, as does the underlying mechanism of economic-demographic interactions. Moreover, with regard to secular growth, the present view emphasizes the independent significance of processes such as technological change and human resource development. However, Alvin Hansen, in modifying Schumpeter's conception to incorporate the building cycle [34], moved in the Kuznets cycle direction. This step was carried logically forward by Isard, who arrived at a view similar in a number of respects to that advanced here. In so doing, Isard explicitly rejected Hansen's secular stagnation thesis, which one suspects, could be shown to run, in one form or another, a conforming Kuznets cycle of its own in economic discussion. Indeed, in striking contrast to the contemporary professional consensus, Isard, writing in 1942, predicted a post-war boom. His reasoning, however, gave undue weight to transport innovation which as has been noted, is not an essential ingredient of the present analysis.

The present analysis may also bear on the problem of delimiting a single phase in the emergence of modern economic growth as an "industrial revolution," "take-off" [56] or "great spurt of industrialization" [30]. The application of such concepts to actual experience has frequently confronted one with the difficulty of deciding among competing periods for such a designation. And, where identified, the duration and other characteristics of the period sometimes correspond to those of Kuznets cycles. It is at least a plausible hypothesis that such an interval, seized upon as a unique phase may be an early and particularly prominent long swing.

III. Recent Experience in the Light of the Model

Viewed in historical perspective, there are a number of similarities between recent and longer term experience, broadly consistent with the crude analytical model sketched above. There are differences, too, however, and on the demographic side, these are so serious as to raise doubts about the model's validity. The present section, after noting some of the similarities, focuses on recent departures with regard to demographic aspects and attempts to reconcile these with the model.

FIGURE 2. AVERAGE (CENTERED) DURING NBER REFERENCE CYCLES OF ANNUAL RATE OF CHANGE OF AGGREGATE PRODUCTION, AGGREGATE CONSTRUCTION, WAGE RATE, AND HOURS, AND OF LEVEL OF IMMIGRATION RATE, NONFARM HOUSEHOLD GROWTH RATE, AND UNEMPLOYMENT RATE, 1830-1964

Note: To facilitate visual comparison of the series, vertical lines have been drawn through the long swing peaks and troughs of the rate of change in aggregate construction, and the area from peak to trough has been shaded.

(Legend continued on following page)

Parallels between Recent and Earlier Experience. The analytical framework suggests the likelihood of longer term fluctuations with roughly similar timing in output growth, labor-market conditions, and household growth, particularly in the nonagricultural sector. For various reasons, other, perhaps independent, movements might occur in these series, but a minimum expectation would be that there would be some semblance of a common longer term rhythm. Is this the case?

Figure 2 assembles series relating to a century or more of U.S. expe-

Legend:

- I. Rate of change of aggregate production, per cent per year.

rience on growth of aggregate output and construction, indicators of changes in labor-market conditions (immigration pre-1914, hours, unemployment, wages), and in household growth (immigration pre-1914 and nonfarm households). A relatively mild smoothing technique has been employed. The values are averages for successive business cycles as identified by the NBER reference chronology, computed both for trough-to-trough and peak-to-peak cycles and plotted at the cycle mid-points. Only one departure was made from this procedure, a departure warranted by the analytical considerations presented previously. The special fluctuations associated with World Wars I and II have been smoothed by ignoring the wartime business cycle peak and first post-war trough.¹⁴ In this way, the cycle average, by balancing the rise in government expenditure against its subsequent decline, becomes a more nearly postwar "normal."

While certain variations in timing exist, it is possible, as suggested by the shading in the figure, to identify swings in the growth rate of aggregate output and construction, labor-market conditions, and household formation, on a roughly one-to-one basis, thus lending some empirical plausibility to the model sketched above.¹⁵ Some of the

¹⁴ Thus, in the case of World War II the peak-to-peak average is for 1937-48 rather than for 1917-44 and 1944-48; and the trough-to-trough average for 1938-49 rather than 1938-46 and 1946-49.

¹⁵ The existence of long swings in the rate of change of wages has been pointed out and analyzed by Clarence Long [51]. A statistically significant association between the annual rate of change of wages and that of unemployment was found by Bowen and Berry [11] in a study covering 1900-58.

swings are quite pronounced, such as those terminating in the 1890's and 1930's; others are milder, such as those ending around World War I and late 1950's. The parallel between the recent period and the experience in the first part of this century has been previously pointed out by Hickman [36]. As noted earlier, a tendency is apparent for the swings in the immigration rate, nonfarm household growth rate, and level of unemployment rate to lag the growth rate of aggregate output, though not without exception.

Several other similarities between recent experience and previous long swings may be noted (for evidence, see [22, 24, 63-66]). The growth rate of manufacturing capital shows a swing, with the capital goods industries tending to precede those oriented toward construction and urban development, as in the pre-1914 period. Spatially, the swing continues to center in nonfarm areas, appearing even more pronounced when more up-to-date census definitions are employed (e.g., metropolitan area rather than urban) and to exhibit wide diffusion among the different geographic divisions of the country. The postwar period has been characterized by an urban and suburban development boom. There has also occurred a swing in internal migration.

Differences in Demographic Aspects. There have, of course, been differences between recent and previous characteristics of long swings.¹⁶ On the demographic side, these relate, not so much to movements in the aggregate variables, that is, growth of total population, total labor force, and total households, but to those in the underlying components of change. Disaggregation of population change into the component parts of births, deaths, and migration is a familiar one. An analogous procedure has been applied here with regard to labor force and household growth as well, as is suggested by the following tabulation:

<i>Population</i>	<i>Labor Force</i>	<i>Households</i>
1. Mortality rate	Mortality and aging	Mortality and aging
2. Net immigration rate	Net immigration	Net immigration
3. Fertility rate	Labor force participation rate	Household headship rate

With regard to labor force growth, the above components have often been identified in the literature, though they are not as rigorously established as in the case of population. With regard to household growth, I owe recognition of the possibility of the present partition scheme to Burnham Campbell [16] (see also [26]). A "headship rate" is defined, along lines identical with that for a labor force partic-

¹⁶ For a more general discussion, see [3, 4, 36].

ipation rate, as the proportion of the population in a given demographic group (e.g., classified by age and sex) who are household heads.

All three of the aggregative demographic variables share in common mortality and migration components. The addition of the aging component to mortality in the case both of labor force and households is necessary because these variables are defined with reference to a population above some minimum age, and thus receive additions in the course of a given period as those initially below the limit grow older. Each aggregative variable also has its distinctive component—fertility rates in the case of population change; labor force participation rates, for labor force; and headship rates, for households. If one were dealing with a geographic subdivision of the national total—for example, the nonfarm sector—internal migration would of course be included with international migration as a component of change.

The alignment in the tabulation of the components underlying the three aggregative variables is designed with a view to facilitating the subsequent discussion. From the viewpoint of demography as such, the components of labor force and household growth on line 1 are analogous to natural increase of the population, i.e., the difference between components 1 and 3 of population growth.¹⁷ The present grouping, however, aims to bring out parallel features with regard to long-swings analysis. Thus, the components on line 1 are largely exogenous to a given long swing; those on lines 2 and 3 are responsive, with line 2 representing a component common to all three variables (migration), and line 3, components which are distinctive. Moreover, since in the subsequent discussion the components on line 3 are frequently referred to collectively, it is convenient to designate each as the "rate" component of its respective aggregate, though this terminology is imprecise.

Figures 3-5 show, for the nationwide values of each of the aggregative variables, the relevant components of change for the period since 1870 or 1880.¹⁸ The basic data—chiefly the decennial censuses—are

¹⁷ A more elaborate analysis would, in fact, further subdivide the components of labor force and household growth on line 1 into, respectively, entries versus exits and formations versus dissolutions. A brief investigation, chiefly for 1930 onward, suggests that the movements shown here in the net balance are overwhelmingly due to the positive elements (entries and formations), just as those in natural increase are typically a reflection of births.

¹⁸ An alternative, or at least complementary, disaggregation would have been desirable for the nonfarm sector alone, but was not feasible with the time and resources available.

A brief word on method: The treatment of population growth is of course standard; in the case of the other two variables, familiar issues, variously characterized as "index number" or "standardization" problems are involved. The solutions adopted here are not claimed to be definitive, though they seem logically consistent with the general analytical framework, but alternative procedures would not alter the present conclusions. With regard to the disaggregation of labor-force growth in a given decade, component 1 was obtained by multiplying the population change of the group due to sources other than current migration by its beginning-of-decade participation rate; the result is the change

FIGURE 3. AVERAGE GROWTH RATE (CENTERED) OF POPULATION BY COMPONENT OF CHANGE, QUINQUENNIALY, 1870-75 TO 1955-60, AND 1960-64 (per thousand per year)

too crude to permit a highly refined analysis relating to such questions as timing and amplitude; on the other hand, they clearly show the swings, and permit certain broad inferences pertinent to the issue under discussion, namely, a comparison between recent and earlier experience. All three figures show the predominant role of net immigration in the swing in the aggregate throughout most of the period

in labor force that would have occurred in the absence of migration or participation rate change. The contribution of participation rate change for each age-sex group is obtained by multiplying the end-of-decade population attributable to sources other than current migration by the excess of the end- over beginning-of-decade participation rates. The migration contribution is obtained as the product of the end-of-decade participation rate and population change due to net immigration during the decade. Thus computed, the components sum exactly to the actual labor-force growth. From 1940 on an identical procedure was used in disaggregating household growth except that headship rather than participation rates were used. Prior to 1940 it was necessary to follow a much more approximate procedure for households, described in the appendix.

FIGURE 4. AVERAGE GROWTH RATE (CENTERED) OF LABOR FORCE BY COMPONENT OF CHANGE, DECENNIALLY, 1870-80 TO 1940-50, AND 1950-55, 1955-60 AND 1960-64 (per cent per decade)

covered, but for the swing from the 1930s through the late 1950s, the distinctive "rate" component for each variable takes charge. Indeed, the movement since 1940—up and then down—of the "rate" component in the three figures is startlingly alike. Clearly this raises a question whether the analytical model suggested in the previous section is indeed relevant to current experience. In that model migration played a key part, filling the dual role of labor-market response and source of household growth; what happens to the model when migration no longer enters into the swing in substantial magnitude?

In part, the answer to this is that migration in the form of *internal* migration does still enter, and to this extent the model is pertinent in its typical form. As noted, recent experience shows a continuation of the historical swings in internal migration [24, 63-66]. On the other hand, although temporal comparisons of the amplitude of internal migration are difficult to make, there seems to be little evidence that the current swing in the rate of internal migration reached greater dimensions than previously, as would be necessary if it were to compensate

FIGURE 5. AVERAGE GROWTH RATE (CENTERED) OF NONFARM HOUSEHOLDS, AND OF TOTAL HOUSEHOLDS BY COMPONENT OF CHANGE, DECENNIALLY, 1880-90 TO 1940-50, AND 1950-55, 1955-60, AND 1960-64 (per cent per decade)

for the damped movement in international migration. Moreover, the actual swings in labor force and household growth, even at the non-farm level, were undoubtedly due in substantial part to the unprecedented movements in the distinctive "rate" components, as well as to internal migration. Reconciliation of these "rate" movements with the analytical model is therefore essential in accounting for the quantitative features of the current swing.

Reasons for Recent Demographic Differences. The nature of the reconciliation is suggested by the model itself. It turns on the suggestion that the character of the labor-market response to a Kuznets cycle in the growth of aggregate demand depends on the nature of labor sup-

FIGURE 6. MALE POPULATION AGED 15-29 AND 30-64, ACTUAL AND PROJECTED, DECENNIALLY 1920 TO 1950, QUINQUENNIALLY, 1955 TO 1985

ply conditions. In the recent swing these conditions were unique in several respects. First, the historical response via immigration was severely curtailed by restrictions imposed since the mid-'twenties, as well as by World War II itself. Second, the contribution to labor force growth of the aging and mortality component reached an unprecedented low (Figure 4). This was an echo effect of the exceptionally rapid decline of the birth rate in the 'twenties and early 'thirties, and was particularly concentrated in the younger working ages, where, so far as one can judge, for the first time in recorded experience, the absolute number of persons aged 15-29 leveled off and actually declined slightly (Figure 6). The relative number, in relation to those aged 30-64, showed a substantial decline (Figure 6, lower panel). Finally, the educational level of younger persons compared to older was disproportionately higher in the recent period than usually (Figure 7). This arose from the rapid expansion of secondary education in the 1920's and 1930's, which temporarily enlarged the educational gap between young and old. While historical evidence is presently lacking, one suspects that it would be necessary to go fairly far back in the nineteenth

FIGURE 7. PROPORTION WITH 9-12 AND 13 OR MORE YEARS OF SCHOOL COMPLETED. POPULATION AGED 25-29 AND 30-64, ACTUAL AND PROJECTED, DECENNIALY 1920-1960, AND QUINQUENNIALY, 1965 TO 1985

century to find a comparable period of rapid acceleration in universal schooling.

In short, in the most recent Kuznets cycle upswing, the relative number of those in young working ages was unusually low, and the relative quality (so far as this depends on formal schooling) was unusually high. These young adults are precisely the ones who in the past played an important part in the quantitative adjustment of labor to the swing in the growth of aggregate demand, as is evidenced by their predominance in migration flows, whether internal or international. The unique labor supply conditions in the recent swing, however, resulted in an exceptionally tight labor market for those in the younger age groups, and gave rise to unusually favorable income growth (and, one suspects, as experience produced evidence of labor-market tightness to those involved, expectations of such growth). In other words, for younger persons, the labor market response took the form predomi-

nantly of a price rather than quantity adjustment.¹⁹ This unusually favorable income situation for younger persons, in turn, induced a sharp reduction in age at marriage and household formation, and a sharp upswing in fertility. This accounts for the abrupt upsurge in the headship and fertility rates. At the same time, the quantitative shortage of younger persons redounded to the benefit of the only labor reserve group available in substantial numbers—older married women who were unencumbered by child-dependency responsibilities.²⁰ As a result, a substantial increase in the total labor force via participation rate change occurred for the first time. Thus, as in the past, an upswing in the growth of aggregate demand was accompanied by labor-market changes and an associated rise in the rate of growth of households which tended to sustain and prolong the boom. Because of the unique labor supply conditions, however, the mechanism of the association was substantially altered, with migration playing a less important role and the “rate” components of change in the demographic variables playing a leading one.

IV. *The Future: Implications of an Echo Effect*

One of the intriguing features of population growth is that it contains within itself a mechanism capable of generating longer term swings. Thus, writing in 1937 about German experience, August Losch states [53, p. 650]:

While the movement of population shows unimportant and irregular [short term] fluctuations which seem to be mere reflections of economic, sanitary and other conditions, we find quite clearly great waves, the main cause of which are the great wars. The deficit of births during a war and the surplus of births in the immediate postwar period repeat themselves about thirty-three years later, when the new generations are at their time of highest fertility. For the same reason thirty-three years later a third wave occurs.

Recognition of this leads naturally to the thought that long swings in economic activity may have their origins in the peculiar structural mechanism of population growth. The present analysis of past U. S. experience, however, does not support this view. Fluctuations in demographic variables have typically arisen from movements in immigration or the “rate” components of change rather than from an echo effect

¹⁹ Historical evidence on income by age is even harder to come by than that relating to quantity adjustments, but various indications in support of this statement are provided in two of my associated papers [20, 23]. The recent estimates of income by age for 1941 by Dorothy S. Brady [12] provide an invaluable prewar benchmark.

²⁰ Elaboration of the statements relating to fertility and household formation is provided in the papers just cited; participation rate change is the subject of a paper now in preparation.

of a surge in births, operating through the aging and mortality component.²¹ Such demographic fluctuations were induced by, rather than initiated, changes in economic activity, although in turn they had important feedback effects. This is not to say that no echo effects at all existed. One can, in fact, trace them in detailed data, but in the past they have been mild, reflecting the fact that before 1940 long swings in fertility were confined to the rate of change rather than to the level of that variable.

Now, however, things have changed. The new demographic developments accompanying the most recent upswing, notably, the dramatic baby boom, have in turn set up an echo effect, currently being felt in the form of a sharp upsurge in the young adult population. What, if any, are the implications of this echo effect for future long swings? Has the economy, perhaps, shifted to a new situation in which long swings are at least partly built-in via a natural demographic cycle, even though this was not the case in the past?

A satisfactory analysis of this question, as of so many on which this paper has touched, calls for a more complete model of long swings. Nevertheless, some tentative impressions may be gained by looking in some detail at the impact of the echo effect on labor force and household growth currently and in the coming decade. Moreover, this is of interest in its own right because of its possible bearing on attempts to assess more generally the outlook for the next decade.²²

The Next Decade. To start with labor supply conditions, the echo effect of the baby boom is currently yielding its fruits in the form of an unprecedented growth in the labor force from the aging and mortality component. Since the first half of the 1950's, the rate at which this source has been contributing to labor force growth has risen from around 5 to 11 per cent per decade, and the projected figure for the last half of the 'sixties is almost 14 per cent. This means that the component of aging and mortality alone will yield in the late 60's a growth rate of the total labor force as high as that *due to all components* in the 1940's and higher than that in the 1950's. The impact of this is concentrated among the younger age groups, with the result that the relative number of those aged 15-29 to 30-64 is now undergoing a rise

²¹ The rise between 1910-20 and 1920-30 in the aging and mortality component, which contributed to a corresponding movement in labor-force and household growth, appears to contradict this observation (Figures 4 and 5). This is primarily due, however, not to an earlier upsurge in the birth rate, but to the fact that the 1910-20 level of this component was depressed sharply below normal by high mortality among young persons resulting from the flu epidemic of 1918. Thus, with reference to Figure 3, the movement is chiefly a reflection, not of a prior fluctuation in the fertility curve, but of a concurrent dip in the mortality curve (inverted), centering on 1910-20.

²² Cf., e.g., [60]. Interestingly, this NTCB study, while not adopting a long swings framework as such, looks at the next decade on the basis of experience in the past two, viewed not as a succession of short cycles, but as a major boom and ensuing retardation.

greater and faster than the preceding decline (Figure 6). Moreover, an independent but significant development is that the advantage of young over old in high school education has declined sharply in the last decade and will decline somewhat further in the next (Figure 7). With regard to college education, the advantage of the young rose somewhat through 1965, but shows little prospect of further increase. On the whole, therefore, a substantial reversal of the preceding period's situation with regard to relative quantity and quality of younger versus older persons is now in progress.

The marked impact of the aging and mortality component on labor force growth suggests that the labor requirements of an upswing in the growth of aggregate demand might for the first time be met very largely from this component rather than from either increased immigration or participation rate change. (One would expect also, of course, a response via internal migration, perhaps taking more the form of a movement among nonfarm centers as the farm reservoir becomes even further depleted.) Would this rather different labor market response be accompanied by an upsurge in household growth as in the past?

One's initial reaction is to say "of course," for the same demographic echo effect that is operating to raise labor force growth is also acting to increase household growth. On investigation, however, several mitigating circumstances come to light.

First, there is a difference in the timing and shape of the impact of the demographic movement on labor force versus household growth. The average age at labor force entry is lower than that of household formation, so that an echo effect tends to raise labor force growth in advance of household growth. This is illustrated in Figure 8, where the contributions of population change to labor force and household growth since the 1930's are compared.²³ Note that the movement in household growth tends to lag that in labor force growth, troughing and then peaking roughly five years later. Moreover, the rise in household growth is somewhat smaller in amplitude and less precipitous than that in labor force growth. This is because among young males the rise in rates of household headship not only centers at a later age than that in labor force participation, but is also less abrupt. As a result, the temporal distribution of an echo effect on household growth is more attenuated than that on labor force growth. Thus while the baby boom does produce an echo effect tending to raise household as well as labor force growth, the former tends to lag the latter and be slightly more spread out over time.

Second, for an echo effect in the population component of change to

²³For convenience of exposition, immigration has here been combined with the aging and mortality effect. The point remains valid if confined to aging and mortality alone since the movements during the period shown are due almost entirely to this component.

raise the *total* growth rate of households—that due to all sources—it is necessary that the headship rate component not decline in compensating fashion. Since the analysis for 1940-55 has already suggested the possibility of a mechanism causing the population and “rate” components to move in at least partly offsetting fashion, it is essential to appraise the outlook for the rate component as well as for the population component. This is facilitated by Figure 9, which for labor force and households repeats the curves of Figure 8 and adds those showing growth due to all sources, actual through 1960-64 and projected through 1975-80.²⁴ For each variable, the vertical difference between the two curves represents the contribution of the rate component.

The startling feature of Figure 9 is that while the echo effect is currently producing and is projected to produce a sharp rise in the growth rate of labor force, an upsurge of comparable magnitude in that of households, even with a lag, is not foreseen. In the case of labor force, to offset completely the echo effect, the contribution of the “rate” component would have to drop to a negative value, that is, participation rates would, on the average, have to decline. This is not the case with regard to households, however. The contribution of the “rate” component has been so high in the past that a drop to a lower positive value, implying merely a retardation in the average rise of headship rates, is sufficient almost wholly to offset the echo effect.

Is a slowing of the rise in headship rates, such as that implied by the projection, likely? Actual experience in the first half of this decade compared with 1955-60 does show such a tendency. Although further study is needed, two considerations suggesting the likelihood of its continuation may be noted, one endogenous and one exogenous. First, even under relatively high employment conditions, the change in relative quality and quantity of young workers now taking place means that they are unlikely to enjoy an excess demand situation comparable to that of 1940-55. Hence, it seems doubtful that a significant contribution to household growth through increases in headship rates will occur among this group. Second, an important factor raising household growth in the past fifteen years has been the noticeable rise in headship rates among the older population, that aged 55 and over, and it is questionable that this will continue at the same pace. A principal factor in this has been the rapid extension of social security coverage. The percentage receiving OASDI benefits in the relevant population groups provides a rough though imperfect indication:²⁵

²⁴ For households, series B projections are used, but the use of series A would not alter the present conclusions, since from 1965 on the growth rates implied by the two projections differ very little.

²⁵ I am grateful to Francisco Bayo, of the Social Security Administration, for the absolute data on beneficiaries, on the basis of which these percentages were computed.

FIGURE 8. CONTRIBUTION OF POPULATION CHANGE TO LABOR FORCE AND HOUSEHOLD GROWTH, ACTUAL AND PROJECTED, DECENNIALLY, 1930-40 AND 1940-50; QUINQUENNIALLY, 1950-55 TO 1975-80 (per cent per decade)

FIGURE 9. AVERAGE GROWTH RATE (CENTERED) OF LABOR FORCE AND HOUSEHOLDS DUE TO ALL SOURCES AND TO POPULATION GROWTH ALONE, ACTUAL 1930-40, '40-50, '50-55, '55-60, AND '60-64, AND PROJECTED, QUINQUENNIALLY, 1960-65 TO 1975-80 (per cent per decade)

———— Growth due to all sources
 - - - - - Growth due to population change

	1950	1963	1975 (projected)
Males, aged 60-64	0	16	22
Males, aged 65+	25	78	89
Females, aged 60-64	0	29	29
Females, aged 65+	17	72	90

Although projections relating to such politically sensitive areas are patently hazardous, the figures provide some warrant for the view that the economy has largely passed through the period when the adoption of social security would have its largest impact on headship rates among the older population. While some additional growth due to this source is probable, its quantitative importance seems likely to be less than in the immediate past.²⁶

To sum up, although a more thorough investigation is needed, the present analysis makes clear that in the current and coming decade, contrary to what one might expect, an upswing in household growth is neither a simultaneous nor automatic accompaniment of a surge in labor force growth arising from the echo effect of the baby boom. True, there is an echo effect exerting an upward pressure on household growth, but it lags that in labor force growth and is more attenuated. In addition, there are circumstances, partly endogenous and partly exogenous, which may dampen this upward pressure by slowing the rise in headship rates among young and old, thereby reducing the contribution to household growth from the "rate" component source. It is far from clear, therefore, under such new circumstances of labor supply, where an echo effect supplies the labor requirements arising from an upswing in the growth of aggregate demand, that a substantial reinforcing stimulus to the boom from an upsurge in household growth like that in the past will occur.

Bearing on Longer Term Future. Though on first glance it is tempting to pronounce that emergence of an echo effect has created a new "built-in" long-swing mechanism, a more careful look at current changes and those in prospect over the next decade creates doubt that any such simple generalization is warranted. However, more study is

²⁶ This discussion bears on Edward F. Denison's criticism [19, p. 531] that "... the long-wave background gets [Burnham] Campbell no farther than others who have based forecasts of housing starts on the normal increase in households that would result from population changes in relevant age-sex groups. . . ." The present analysis suggests that not only the population component of household change should be studied, but also the "rate" component, and that the long swing approach may be of value in clarifying the movements in the "rate" component. The reference to OASDI, however, shows clearly that other factors are pertinent and that more intensive study is needed of the determinants of headship rate changes, including factors such as school enrollment and marital status. Clearly, throughout this paper, no attempt has been made to consider the possible bearing of the Viet Nam War.

needed of the determinants of household growth, including attention to "gross" changes (formations and dissolutions) and the expenditure implications thereof, by age. (Clearly, the expenditure implications of social security's forestalling dissolution of a home are likely to be quite different from those arising from accelerated household formation among young persons.) The relative weight of endogenous versus exogenous elements in labor force and household growth needs clarification too. For example, while the present analytical scheme suggests with regard to both labor force and household growth that there is a tendency for movements in the "rate" and population components to be at least partly offsetting, the dampening at present appears to be greater for household growth. Is this attributable wholly to exogenous circumstances or is it partly inherent in the mechanism? Moreover, perhaps undue attention has been given here to demographic reactions from the side of household growth. In commenting on this paper, Abramovitz points out that, in addition to such considerations, accelerated growth in labor force, for whatever reason, may act, at least permissively, to sustain a protracted boom by keeping the "natural rate" of output growth above the "warranted rate" for a longer period, thus postponing the time when an output ceiling may act as a brake on long term capital investment.

Certainly the emergence of demographic echo effects is a new phenomenon which must be reckoned with in assessing the longer term future. For example, another possibility, though not the only one, is that, on the one hand, an echo effect creates a tendency toward waves in labor force growth with a duration longer than Kuznets cycles, and, on the other, upswings in the growth of aggregate demand initiated by non-demographic factors occur with the frequency of past Kuznets cycles. Under such circumstances, the impact of the demand movement on the labor market and the reactions stemming therefrom could be highly variable, depending on whether the flood, ebb, or some intermediate stage of labor force growth was prevailing at the time. In this connection, it should be noted that the current decline in the crude birth rate has, in only eight years, wiped out the increase since 1940. (This is not true, however, of age-adjusted fertility measures.) Beyond 1975, this will produce a shift in relative numbers of young and old in a direction similar to that of the 'forties and early 'fifties (cf. Figure 6). If aggregate demand conditions are favorable, this creates the possibility of economic-demographic interactions at that time like those of the post-World War II era.

Finally, there is nothing in this analysis which implies that Kuznets cycles in the economy's growth rate are not susceptible to elimination via appropriate policy measures. If the emphasis on the central role of

aggregate demand is correct, then, as Abramovitz and Hickman have also suggested, manipulation of effective demand should make it possible largely to eliminate discernible long swings. But the analysis does imply that determination of the appropriate policy measures may call for more attention to variables and relationships of the type suggested here than has been customary in the past.

V. *Summary*

The present paper, building on the work of numerous predecessors, suggests that one of the mechanisms responsible for long swings in economic growth may involve interactions among aggregate demand, labor-market conditions, and household growth, with a feedback effect from the last to the first. An upswing in the growth of aggregate demand and the growing labor-market tightness induced thereby engenders accelerated marriage, migration, and household growth. These are critical decision points in the life cycle, entailing spending commitments extending over several years as a new home is established and a family started or settled. In effect, such commitments are geared to a notion of permanent income and thus tend to be relatively insensitive to short term income changes. A bunching of such commitments serves to cushion the economy against the usual business cycle and becomes exhausted only gradually.

Such a bunching of long term spending commitments may be the key to Kuznets cycle phenomena. This applies not only to decisions of households but other spending units as well, though no attempt is made here to examine changes in the population of business or governmental units. The investigation stops short too of exploring financial aspects of the swings as well as possible accelerator-type relationships. Whether Kuznets cycles may be self-generating is left open; no more is claimed than that a plausible mechanism has been identified which once initiated, for whatever reason, might help to sustain the economy over a period longer than the usual business cycle.

The paper touches too on the relation of this possible long-swing mechanism not only to business cycles but to secular development as well. Such swings are prevalent in the historical development of free market economies, it is suggested, because typically the adoption of modern industrial technology has required redistribution of the population from rural to urban areas and the provision of the requisite goods and services for this relocated population. The induced stage of the Kuznets cycle mechanism, an urban development boom, is essentially the accomplishment of this requirement in a free market economy by a multiplier-type process.

The analytical scheme creates the expectation that series on aggre-

gate output and construction, labor-market conditions, and household growth, particularly with regard to the nonagricultural sector, would show some semblance of longer term fluctuations with roughly similar timing, and U. S. experience over a century or more bears this out. The post-World War II boom and subsequent slackening in the economy's growth rate form a consistent part of this record. However, on the demographic side some important differences appear. In the recent period, swings in population, labor force, and household growth were chiefly due, not to an immigration swing as was typically the case in the past, but to movements in, respectively, the birth rate, labor-force participation rates, and headship rates. These new developments are attributed to the unusual labor supply conditions prevailing in this period. Young adults—those who in the past played a central role in the quantitative adjustment of labor to a swing in the growth of aggregate demand—were in exceptionally short supply and their educational advantage over older persons was unusually high. As a result they enjoyed an exceptionally favorable labor-market situation, and this, in turn sharply accelerated marriage, household headship, and fertility. Thus an upswing in the growth of aggregate demand induced via its labor market impact an increase in household growth, but through a different channel than in the past. At the same time, the quantitative shortage of younger persons redounded to the benefit of the only secondary labor force group available in substantial numbers—older married women unencumbered by small-child responsibilities—and led to an unprecedented rise in their labor-force participation rates.

The unique demographic developments of the most recent swing, notably the dramatic baby boom, have created a demographic situation in the current and coming decade different, in turn, from both the recent and more distant past. A sharp upsurge in the young adult population is occurring as an echo effect of the baby boom. Whereas the interpretation of previous U. S. experience presented here sees demographic swings as primarily induced by, rather than initiating, economic movements, the appearance for the first time of a substantial echo effect raises the question whether the economy has perhaps shifted to a new situation in which long swings are partly built in via a natural demographic cycle. An exploratory investigation for the current and coming decade suggests that with an echo effect primarily supplying the labor requirements of an upswing in the growth of aggregate demand, it is uncertain whether a substantial reinforcing stimulus from an upsurge in household growth will also occur. This is because, while the echo effect does exert an upward pressure on household growth, it occurs with a lag, and is dampened by circumstances reducing the rise in headship rates among young and old. Since these circumstances are

partly endogenous, involving an unfavorable shift in the relative number of young adults as a concomitant to the echo effect, any generalization about a built-in demographic long-swing mechanism seems premature in the absence of more intensive study. An alternative possibility, though not the only one, is for swings in the growth of aggregate demand to occur in conjunction with a longer duration movement in labor force growth via the echo effect. This would engender a variety of demand-supply combinations in the labor market, with correspondingly variable reactions stemming therefrom.

As for policy, the present analysis suggests that more attention to variables and relationships of the type suggested here may be desirable. If the emphasis on the central role of aggregate demand rather than supply conditions in initiating these movements is correct, then appropriate stabilization measures might eventually lead to the virtual extinction of Kuznets cycles.

APPENDIX: SOURCES AND METHODS FOR FIGURES 1-9

Figure 1

Series 1. [29, p. 127].

Series 2. 1900-28, [89, pp. 138-39, T. I-16, 1. 5]; 1929-62, [73 (Jan. 1964), p. 210, col. 1]; 1963, [73 (Jan. 1965), p. 192, col. 1].

Series 3. 1860-1941, [25, p. 34]; 1942-1948, NBER files.

Series 4. NBER files.

Series 5. [1, pp. 151-52, series 21a].

Series 6. [1, pp. 151-53, series 21]. Extrapolated from 1959 to 1964 by annual per cent change in [73 (Jan. 1965), p. 234, col. 4].

Series 7. Immigration: [86, series C 88]. Population: 1820-68, [86, series A-2]; 1869-1899, [41, unpublished annual estimates underlying pp. 624-6, Table R-37, col. 9]; 1900-07, [84, no. 250, p. 6], adjusted to include armed forces overseas by unpublished annual estimates underlying [41, *ibid.*, col. 8].

Series 8. Immigration: 1908-1945, [45, p. 96, immigrants minus emigrants], extended to 1961 via [86, 87, series C-140 and C-156]. Population: 1908-16, 1920-29, same as for series 7 for 1900-07; 1917-19, 1930-61, [84, no. 250, p. 6, tables 2, 3].

Series 9. 1820-1957, [86, sum of series U 185-190]; 1957-62, [88, 1963, p. 854].

Figure 2

Series 1. Preliminary unpublished annual estimates (as of April 1964) in millions of 1860 dollars by Robert E. Gallman, underlying [71, pp. 27, 34]. Nonperishable commodity output is the sum of consumers' semi-durables and durables, manufactured producers' durables, and gross new construction.

Series 2. [29, p. 127].

Series 3. [40, pp. 293-4, col. 11].

Series 4. Same as for Figure 1, series 2.

Series 5. Same source as for series 1.

Series 6. [1, pp. 141-2, series 5, segment I].

Series 7. 1900-58, [1, pp. 142-145, series 2]; extrapolated from 1954-58 to 1957-60 and 1958-61 assuming change in rates between successive periods was same as that shown by [73 (Jan. 1964), p. 210, col. 7, and, for 1960-64, 73 (Jan. 1965), p. 192, col. 7].

Series 8. [59, p. 303].

Series 9. 1900-58, [51, pp. 150-51, col. 5]; 1959-64, col. 1 of same source was extrapolated on basis of absolute annual change in [74 (March 1966), p. 59, col. 3], and col. 4 via [73 (Jan. 1965), p. 244, col. 1].

Series 10. [39, p. 375].

Series 11. [74 (April 1965), p. 33, col. 2]

Series 12. Same as for Figure 1, series 7.

Series 13. [86, 87, series A-243]; 1964 value from [83, no. 130, p. 1].

Series 14. 1890-99, [47, p. 522]; 1900-32, [90, p. 215].

Series 15. [74 (March 1966), p. 23].

Figure 3

The break in series in 1950-55 is due to the shift in sources described below.

1870-1955

Except as noted subsequently, the basic source was [42, p. 37, t. 1, col. 4; p. 39, t. 3, col. 5; p. 41, t. 5, col. 7; and p. 43, t. 6, col. 5 (underlying unrounded quinquennial estimates were used)]. However, for net migration, 1910-40 data were from [45, pp. 95-96, t. B-1]. For 1940-55, estimates for all series were revised somewhat, the chief differences from the original source being to include deaths to armed forces overseas and to keep the scope of the net migration estimate the same as for the pre-1940 period.

The sum of the components does not exactly equal total increase, because net migration refers to alien arrivals less departures, and thus includes some nonmigratory movements. Pure migration estimates are not available prior to 1910.

1950-64

[84, no. 302, p. 8]. Estimates for fiscal year were divided by Jan. 1 population to obtain annual rates, which were then averaged for periods shown.

Figure 4

For method of computing component contributions to total change, see text, footnote 18. Computations were done for most detailed classifications available (identified below for each period) with higher levels of aggregation being obtained by summation. The break in series in 1890-1900 is chiefly due to the replacement of a regional by an age classification in the calculations; in 1940-50, by a shift from census to Current Population Survey data.

1870-1900

The series covers all population classes except nonwhites other than Negroes. For 1870-1890, the calculations were done separately for native born and foreign born in each of the four census regions (no separation by sex was

possible); for 1890-1900, for native white, Negroes, and foreign born white, by sex, in each of the four regions. An overlap comparison for 1890-1900 of the pre- and post-1890 methods yielded similar results with regard to total U.S. change and the two sets of calculations were therefore treated as continuous. The sources of the basic data necessary for the calculations were as follows.

Labor force. 1870, 1880, census reports. 1890, 1900, tabulations of census data prepared by Ann R. Miller, University of Pennsylvania Population Studies Center. For the present study, the 1870 data were adjusted for underenumeration in the South as estimated by Alba M. Edwards [79, p. 141]; the 1890 data, for underenumeration of children aged 10-15 as described in [78, pp. lxvi-lxxi, cviii, clv].

Population. All dates from census reports. Data for 1870 were adjusted for underenumeration in South as estimated by Edwards, *op. cit.*

Migration. [48, Table P-1].

1890-1950

All classes of the population are covered. The calculations were done separately for each sex-age class of native whites, nonwhites, and foreign born whites. Through 1930 the population aged 10 and over is included, thereafter, that 14 and over. An overlap for 1920-30 indicates the negligible effect of eliminating those aged 10-13. Other age classes used were 14-19, 20-24, 25-44, 45-64, 65+.

Labor force. 1890-1940, from unpublished unrounded data underlying [52, Appendix A]. 1950, the estimate was built up from the census reports, and the total differs slightly from that shown by both Long and the census because it was obtained by summing components which included estimates. The latter were necessitated by lack of complete count data and/or sufficient component detail in the census.

Population. 1890-1940, tabulations of census data by Everett S. Lee, University of Pennsylvania Population Studies Center. 1950, data taken directly or estimated from census report.

Migration. [48, Table P-1]. Migration for those aged 14-19 was assumed same as that for those aged 15-19. Age groups 15-19 and 20-24 were from unpublished underlying data.

1940-64

Covers total population including armed forces overseas. The calculations were done separately for each sex-age class, but no color-nativity or geographic components were distinguished. The age classes were 14-19, 20-24, ten year groups through 55-64, and 65+, except that for the period after 1960, the 14-19 were subdivided into 14-15, 16-17, and 18-19.

Labor force. 1940, [82, no. 2 (no date), p. 11]. Unpublished age detail comparable to 1950 was kindly provided by Gertrude Bancroft, Bureau of Labor Statistics. To these figures were added 150,000 members of the armed forces who were outside the continental United States in 1940. See *ibid.*, p. 1, and [74, vol. 6, no. 1 (July 1959), p. 1, n. 1]. The age-sex distribution for

his group is from [84, no. 98 (Aug. 13, 1954), pp. 7 and 15]. 1950, [82, no. 85 (June 1958), p. 5]. Published estimates were adjusted upward in same way as for 1940. For explanation, see references cited for 1940. 1955, [77, p. 53]. 1960 (*excluding Alaska and Hawaii*), [74, vol. 7, no. 7 (Jan. 1961), p. xii, T. 2]. 1960 (*including Alaska and Hawaii*), [75, p. 4]. 1964, [76, p. 130].

Population, 1940, [84, no. 98 (Aug. 13, 1954), p. 15]. 1950, [*ibid.*, no. 146 (Nov. 12, 1956), p. 10]. 1955, [77, p. 52]. 1960 (*excluding Alaska and Hawaii*), unpublished estimates prepared with reference to 1950 census. These data, provided by Bureau of Labor Statistics, are consistent in latter regard with the 1960 labor force estimates excluding Alaska and Hawaii. Alaska and Hawaii were eliminated by deducting 1960 census data for these states. 1960 (*including Alaska and Hawaii*), [75, p. 4]. 1964, [76, p. 130].

Migration. 1940-50, migration total from [84, no. 223 (Jan. 26, 1961), p. 4]. Age-sex distribution was assumed to be in same proportions as in [*ibid.*, no. 98 (Aug. 13, 1954), p. 18]. A small deduction was made to allow for mortality among migrants between year of immigration and end of decade, based on survival rates employed in [*ibid.*, no. 187 (Nov. 10, 1958), p. 13]. 1950-60, total and age-sex distribution of migrants (*excluding Alaska and Hawaii*) surviving to end of decade from unpublished estimates made by Gladys Bowles, kindly provided by Bureau of Census. For all age groups, the decade total was distributed between quinquennia according to the proportions shown for total migration in [*ibid.*, no. 302 (Mar. 11, 1965), p. 8]. 1960-64, migration total from *ibid.* Age-sex distribution was assumed same as that of migrants used in 1964 population projections [84, No. 286 (July 1964), p. 27].

Figure 5

1880-1940

Total households. 1880-1920, [86, series A-255]; 1910-1940, [*ibid.*, series A-242].

Nonfarm households. 1880-1920, total households less farm households [85, p. 6]; 1910-1940, [86, series A-243]. The break in 1910-20 reflects a shift from census levels to estimates consistent with those of the Current Population Survey.

With regard to components of change, although estimates are available for the total number of households at each census date, lack of detail by sex and age for several of the censuses prevented use for the period before 1940 of the partition technique described in the text for households post-1940 and for labor force. After some experimentation, the following procedure for approximating the components was adopted:

a. Contribution of aging and mortality. For each decade the absolute change due to aging and mortality in the population of both sexes aged 25 and over was weighted by .44, and in the population 20-24 by .10, the weights representing the approximate headship rates for these population groups. Summation of the results gave an estimate of the absolute change in households due

to this population component. This was then converted to a percentage change by dividing by the average of the initial and terminal number of households for the decade.

b. Contribution of net migration. Assumed the same as the contribution of net migration to the percentage change in population aged 25 and over.

c. Contribution of headship rate change. Assumed the same as the change in the age-standardized proportion of males aged 14 and over married. The absolute change over the decade was converted to a percentage basis by dividing by the average of the initial and terminal marriage proportions for the decade.

Estimates of the components of population change by sex and age needed for (a) and (b), prepared for the University of Pennsylvania Study of Population Redistribution and Economic Growth, were kindly provided by Dr. Hope T. Eldridge. The headship rate weights of .10 and .44 are approximately those for the age groups 20-24 and 25+ in the 1890 and 1930 censuses. The age-standardized percentage of males married was from [86, series A-216].

The rationale of the procedures is that the contribution to household growth of the two demographic components (a and b) tends to conform closely to their contribution to growth of the population of household forming age. For component (a) an allowance is needed for differences among age groups in household headship. With regard to the rate component, marriage and household headship among males tend to be closely associated. Hence the movement in the former provides an approximation to the latter.

An indication of the validity of the approximation may be obtained by comparing the sum of the components with the total for each decade 1870-1940. The results correspond fairly closely for each period, and, of particular importance for the present purpose, the general pattern of change over time is quite similar. Another test is provided by applying the approximation technique to 1940-50 and comparing the results with those of the more refined procedure:

Household Growth (per cent) Due to:					
	All Sources	Sum of Components	Aging and Mortality	Net Migration	Headship Rate Change
Refined procedure (1940-50 data in Figure 5)	21.7	21.7	13.1	1.8	6.8
Approximation	—	23.1	14.4	0.7	8.0

Although there are small differences, the approximation procedure correctly shows that the source of the sharp rise in household growth from 1930-40 to 1940-50 is due to the movement in the rate component, and that the demographic components played a negligible part in this rise.

1940-64

The method followed for estimating components of change was the same as that for labor force, and is described in the text, footnote 18. Household data refer to the civilian noninstitutional population plus members of the armed forces living off post or with their families on military reservations; population data, to the total population, including armed forces overseas. Calculations were done separately for each sex-age class of the total population. Age classes were 14-24, 25-29, 30-34, ten year groups through 55-64, and 65+. Alaska and Hawaii are omitted in calculations referring to periods through 1960, but are included in those for 1960 on.

Households. 1940, [81, p. 1-458]. 1950, [83, no. 33 (Feb. 12, 1951), p. 15]. 1955, [*ibid.*, no. 67 (May 2, 1956), p. 11]. 1960, [*ibid.*, no. 106 (Jan. 9, 1961), p. 13]. An estimate excluding Alaska and Hawaii was obtained by deducting 1960 census data for these states. 1964, [*ibid.*, no. 139 (June 11, 1965), pp. 17-18].

Population and migration. Same as for Figure 4, 1940-64.

Figure 6

1920-30 [80, p. 1-93]; 1940-50 [84, no. 98, p. 15]; 1955. [*ibid.*, no. 265, p. 25]; 1960-85 [*ibid.*, no. 286, p. 42, series C].

Figure 7

1920-40, [80, p. 1-238]. The 1920 and 1930 values were inferred from those for the appropriate cohorts as reported in 1940, the first date at which data on educational attainment were collected. 1950 [*ibid.*, p. 1-236]; 1960-85, [84, no. 305, pp. 7-10].

Figures 8 and 9

For periods through 1960-64, values are same as those in Figures 4 and 5, except that the "population growth" component is the contribution due to net migration plus that due to aging and mortality. For sources and methods see those for Figures 4 and 5.

The method by which the quinquennial projections from 1960-65 through 1975-80 were partitioned is that described in the text, footnote 18. Scope and classification detail were the same as those for the 1960-64 period described under the head of 1940-64 calculations of Figures 4 and 5. Sources of basic data were as follows.

Labor force. 1965-75 (*based on 1962 population projection*), [75, p. 4]. 1970-80 (*based on 1964 population projection*), [76, p. 130].

Households. 1965-80 (*based on 1962 population projection*), [83, no. 123 (April 11, 1963)]. Unpublished distributions by age and sex were provided by the Bureau of the Census.

Population. 1965-75 (*1962 population projection*), [75, p. 4]. 1980 (*1962 population projection*), [84, no. 251 (July 6, 1962), p. 4, series II]. 1970-80 (*1964 population projection*), [76, p. 130].

Migration. 1960-75 (*1962 population projection*), quinquennial projection from [84, no. 187 (Nov. 10, 1958), p. 13]. In accordance with assumption used in census projections, all migrants were assumed to survive to the end

of the quinquennium in which they immigrated. 1960-80 (1964 population projection), annual projection in [84, no. 286 (July 1964), p. 27] was cumulated and aged to end of quinquennium, assuming no mortality among migrants.

THE POSSIBILITY OF A SOCIAL WELFARE FUNCTION

By JAMES S. COLEMAN*

Ever since 1951, when Kenneth Arrow published his monograph showing the paradox that social welfare functions generate, there has been interest in overcoming or bypassing this paradox.¹ The paradox is that, given certain simple and very persuasive conditions for collective rationality, there can be no decision rule which meets these conditions. The conditions, simply stated, are these:

1. Between three alternatives, the social welfare function must give rise to a unique social ordering, no matter how individual members of the group choose to order the three alternatives.
2. The social ordering must correspond positively, or at least not negatively, to changes in the ordering of any one individual.
3. The elimination of any one alternative shall not affect the ranking of the other alternatives in the social welfare function.
4. Voters can choose freely among all alternatives.
5. No one individual's choice can dictate the social ordering independently of the choices of others.

It is easy to show that even with three voters and three alternatives, a situation can exist in which these conditions are not met by a simple majority vote. For consider three voters, *X*, *Y*, and *Z*, and three alternatives, *A*, *B*, and *C*. The rankings given by *X*, *Y*, and *Z* are:

Rank	<i>X</i>	<i>Y</i>	<i>Z</i>
1	<i>A</i>	<i>B</i>	<i>C</i>
2	<i>B</i>	<i>C</i>	<i>A</i>
3	<i>C</i>	<i>A</i>	<i>B</i>

Now if we eliminate alternative *C*, *A* is preferred by *X* and *Z*, and

* The author is professor of social relations at The Johns Hopkins University. He is grateful to a number of persons, especially James Buchanan, Carl Christ, Arthur Stinchcombe, and Gordon Tullock, for comments on an earlier draft.

¹ See Kenneth Arrow [1]. Jerome Rothenberg [9] discusses in detail the main lines of the work subsequent to Arrow in his review and synthesis of the literature on social welfare. Some of these approaches are in the same spirit as the present paper, though none, so far as I know, take the position taken in this paper, or arrive at similar conclusions. Hildreth [5] says, for example "Suppose that in Case I (individual) *i* barely prefers (alternative) *X* to *Y*, and *j* desperately prefers *Y* to *X*. In Case II let *i* desperately prefer *X* to *Y* and *j* barely prefer *Y* to *X*. By Arrow's Condition 3, the social ordering between *X* and *Y* must be the same in Case I as in Case II. Admittedly our facilities for distinguishing bare preferences from desperate preferences may often be questionable, but we have to decide whether or not this justifies us in excluding all variations in degrees of preference from consideration."

therefore wins. Thus we say that the social welfare function generates a social order AwB (where " w " means A wins over B). When we eliminate alternative A , B is preferred by X and Y , and therefore wins. Thus BwC . Finally, if B is eliminated, C is preferred to A by Y and Z , and therefore wins. Thus CwA . However, this produces an inconsistent social ordering, since AwB , BwC , but CwA .

I want to suggest in this paper that this approach to a social welfare function leaves out of consideration precisely those elements which are most crucial in empirical cases of social choice, and that it is this omission which creates the apparent paradox. This omission allows the problem to be conceptualized in such a way that the third condition above appears to be very "reasonable," while from the point of view of individual rationality it is not.

Quite simply, I suggest that this approach, by looking at only the surface characteristics of social decision rules, neglects the most important element that nearly all such rules contain: a means for allowing the expression of relative intensities of preference, or of differences between utilities associated with alternatives. I suggest, in other words, that Arrow's impossibility theorem is relevant only to those social choice mechanisms in which it is not possible to express relative intensities, and that when it is possible to express such intensities, condition 3 is inconsistent not only with "collective rationality" but with individual rationality. That is, the elimination of an alternative, though it be very low in his ordering, may change the rational individual's behavior.² I will also suggest some of the most important mechanisms, in actual societies, through which individuals may express intensities.

I suggest that the appropriate way to examine such problems of individual choice and social welfare is akin to the method of studying utility under risk. That is, when the outcome of a decision is uncertain, then each individual attaches to each possible outcome a subjective probability, and thus to the decision an expected utility. If he has various kinds of behavior that he can carry out, then he will act in such a way as to maximize the expected utility.

In any collective decision or "social choice," the outcome is not determined by the individual's action alone. Thus in order to behave rationally, he must estimate the expected utilities of each action open to him. These expected utilities are contingent not only on the utility of each outcome to him, but on the probability he estimates it to have under each action open to him. Consequently, the behavior of indi-

² I should note here that the approach of devising a social welfare function which should meet criteria of "collective rationality" is not one which is in general consistent with positive economic theory. It is much more appropriate to look for decision functions which are defined in terms of the rational behavior of individuals, such as the principle of Pareto optimality.

viduals in collective decisions must be governed by rationality under uncertainty or risk, not by rationality under certainty. It follows from this that the rational individual must express not only the ordering of his utilities for the possible outcomes, as he does in rationality under certainty, but also the relative sizes of utility differences between various outcomes, as he must do in rational behavior under risk.

It could be said that this approach violates the spirit of Arrow's approach, because Arrow was concerned merely with the ordering of tastes in the community, and showed that no aggregation of these ordered tastes could be consistent, in the sense of meeting his conditions for reasonableness or social rationality. The flaw in this argument is that citizen sovereignty, which is one of Arrow's conditions, implies the *expression* of these tastes or preferences, the expression that is normally embodied in voting, with the voting rule serving as the aggregation device for the society. Once this is allowed, then as indicated above, it becomes irrational for an individual to express only his preferences, and not something more which would maximize his expected utility. This "something more" can be variously characterized as his intensity of preference or the relative sizes of utility differences between outcomes.

Thus it is not correct to establish a relation between individual choice and social choice which uses as a model individual choice under certainty. As a subsequent example will indicate, only under a very special condition does the rational individual's behavior become like that of the rational actor under certainty.

It should be pointed out that the use of intensities of preference in relation to social choice, as derived from conceptions of utility under risk, is nothing new. Rothenberg, in his review of work subsequent to Arrow's, discusses in detail the use in social welfare functions of expected utility deriving from von Neumann-Morgenstern's definitions of utility under risk [9]. But in all these approaches, the expected utility has been imported, so to speak, from some supposed external measurement, and does not derive from the very behavior itself in the collective decision.³ Such an approach leads these authors to question whether it is "legitimate" to introduce intensities through use of cardinal utilities. (For example, Rothenberg says, "Assuming that we can 'measure' preference intensities with a tolerable degree of precision, is this the kind of factor which we *ought* to treat on a par with preference ordering in the context of social choice?" [9, p. 139]. This approach is a carry-over from an earlier and more naive view of social welfare, in which it was assumed that the economist, as advisor to the policy-maker, could assess the

³ Peter Newman [7] has, however, explicitly recognized that individual behavior in collective choice must be governed by rationality under uncertainty, rather than certainty.

tastes of individuals through some sort of measurement, and then tell the policy-maker what was best for the people—always in terms of their own tastes. In fact, however, it is the political process itself which, together with the existing structure of collective decision-making, expresses these tastes. Only more recently in work like that of Duncan Black [2], Downs [4], Buchanan and Tullock [3], and Olson [8], and earlier in the individualist school of public finance stemming from Wicksell, have economists given the individual the same autonomy to express his interests in collective decisions that they have long allowed him in market behavior.⁴

I. The Rational Individual in Collective Decisions

The simple example of three individuals and three alternatives given earlier can be used to illustrate how rational individuals may be expected to behave in collective decisions, and some of the implications for the system. We will consider the individuals in the following circumstances:

- a. They can only vote, and have no information about others' votes.
- b. They can vote, but they also have some information that allows them to estimate probabilities of others' votes.
- c. They can not only vote on the social decision, but also have another decision on which to make a choice. They can make any agreements they desire in the negotiations preceding the vote.

A. Only Voting on a Single Issue with No Information

Let us think of a quantity U_{xa} , which is the utility of outcome A to individual X . The properties that this quantity will obey depend on the kind of behavior allowed to X . That is, although we may consider that in reality X does have some "amount of utility" which he associates with A , we will treat this "amount" as if it had only limited properties, depending on the behavior which we allow the individual. The wider the range of behavior allowed, the nearer this "amount" will come to have the properties of a real number.

If individual X does not know the preferences of Y and Z , then we can calculate the expected utility of this decision for him as follows, under a majority rule.⁵ Under this complete absence of knowledge about Y 's and Z 's preferences, all possible combinations of Y 's and Z 's vote have equal subjective probability for him. Thus a table can be set up as indicated below:

⁴ Wicksell's and Lindahl's approaches to the theory of public finance are probably as closely allied in spirit to the present paper as any of the subsequent approaches.

⁵ Such a decision rule as a majority rule would need an additional rule in case no alternative attained a majority. Such a rule we posit to be a random mechanism with probabilities for each alternative proportional to the number of votes it received. In this case, $p_a = p_b = p_c = \frac{1}{3}$.

Votes of		Outcome if X	
Y	Z	Votes for A	Probability
A	A	A	$1/9$
A	B	A	$1/9$
A	C	A	$1/9$
B	A	A	$1/9$
B	B	B	$1/9$
B	C	$1/3 A, 1/3 B, 1/3 C$	$1/9$
C	A	A	$1/9$
C	B	$1/3 A, 1/3 B, 1/3 C$	$1/9$
C	C	C	$1/9$

The outcomes are similar, but in favor of B and C , if he were to vote for B or C respectively. If we label X 's vote for A , B , or C , X_a , X_b , and X_c , respectively, the expected utility of this decision for him, if he knows nothing about Y 's and Z 's preferences, is:

$$(1) \quad E(U_x | X_a) = 17/27 U_{xa} + 5/27 U_{xb} + 5/27 U_{xc}$$

$$(2) \quad E(U_x | X_b) = 5/27 U_{xa} + 17/27 U_{xb} + 5/27 U_{xc}$$

$$(3) \quad E(U_x | X_c) = 5/27 U_{xa} + 5/27 U_{xb} + 17/27 U_{xc}$$

Clearly, if $U_{xa} > U_{xb} > U_{xc}$, then subtraction will show that $E(U_x | X_a) > E(U_x | X_b) > E(U_x | X_c)$, and he will carry out action X_a if A is an available alternative and X_b if only B and C are available. Since this is the only action available to him, the only information we have concerning the utilities as a result of his behavior is an ordering. (Alternatively, the only property we need to attribute to the utilities to predict such behavior is their order.)

B. Vote on a Single Issue, with Information about Others' Preferences

If X has the same behavior alternatives available to him, but has in addition information about the ordering that Y and Z give to A , B , and C , and assumes they will vote their preference, his assessment of the situation is this:

Votes of		Outcome if He Votes for:			Probability
Y	Z	A	B	C	
B	C	$1/3 A, 1/3 B, 1/3 C$	B	C	1

Under the belief that Y and Z will vote for B and C respectively, his expected utilities are:

$$(4) \quad E(U_x | X_a) = 1/3 U_{xa} + 1/3 U_{xb} + 1/3 U_{xc}$$

$$(5) \quad E(U_x | X_b) = U_{xb}$$

$$(6) \quad E(U_x | X_c) = U_{xc}$$

Now his behavior is not fully determined by the order among U_{xa} , U_{xb} , and U_{xc} . For if U_{xc} is small, relative to U_{xb} and U_{xa} , so that

$$(7) \quad 1/3 U_{xa} + 1/3 U_{xb} + 1/3 U_{xc} < U_{xb}$$

then he will choose to take action X_b rather than X_a . This situation is exactly that of the hypothesis used in measurement of utility under risk, where his behavior in a choice between risky alternatives is used to provide information about the size of utility differences between different alternatives. Rearranging the inequality above gives the following relation, if he chooses alternative B :

$$(8) \quad U_{xa} - U_{xb} < U_{xb} - U_{xc}$$

That is, if he chooses B although he prefers A , the utility difference between alternatives A and B is less than that between B and C .

Of course, the same analysis may be applied to the other individuals Y and Z , with the result that each person might vote for his second choice because he assumes that the others will vote their first choices. However, such a peculiar result does not make the behavior less rational for him. It means merely that he incorrectly assessed the probabilities of the others' votes.⁶ If he had knowledge, or some degree of belief, that those votes would be cast for other than alternatives B and C respectively, then the appropriate subjective probabilities would modify the coefficients in equations (4), (5), and (6). The important point is that when he no longer estimates the probabilities of others' votes to be equal for each alternative, the degenerate case of equations (1)–(3) no longer holds, and his behavior will depend on the size of the utility differences between pairs of outcomes, as in (8).

Thus, even in this case of actions limited to a single vote, a comparison of utilities beyond simple ordering can come about. If he takes action X_b (a vote for B), this implies equation (7), or rearranged,

$$U_{xb} < 1/2 U_{xa} + 1/2 U_{xc},$$

under the expected utilities indicated in equations (4), (5), and (6). That is, if he prefers A to B to C , but votes for B , knowing that Y will vote for B and Z for C , then this means that B is "closer to" A in utility

⁶ A game-theoretic definition of rationality would include an estimate, in the absence of other information, of the probabilities associated with others' actions. In game theory, the estimate is that the other persons will use the same rules one does oneself. This would require an assessment of double contingencies by each individual, and require the addition of some arbitrary rule, such as von Neumann's minimization of maximum loss, in order to make the behavior determinate. Because any such rule is arbitrary, it is outside the scope of what one wants within the definition of rationality. And because the assumed situation of complete absence of information about the others' actions, on which this definition of rationality would depend, is only one point in the space of all possible information states, there is still less reason to accept the von Neumann definition.

for him than C is to B . Note that because the individual must calculate expected utilities of the outcome, no outcome is "irrelevant," so long as there is some subjective probability of its occurrence. In fact, in this case, the utility of C for X plays a crucial role in determining whether he will vote for A or B . Thus the elimination of C might have—and legitimately so from the point of view of individual rationality as well as social welfare—an effect upon the outcome.⁷

C. *Another Collective Decision, with Vote Exchanges*

The behavior available to the individual in the above cases is not enough to express much about the utilities that various alternatives have for him. Neither does it correspond to the behavior available to members of decision-making bodies, such as city councils, legislatures, town meetings, or social groups. In any such body, the individuals, in attempting to maximize their expected utilities, will use whatever power they possess. The principal kind of behavior that is available to them in nearly all cases is a sequence of decisions. The essential properties that such a sequence introduces are shown by introducing a single new decision, with alternatives labelled similarly to the first. The orders by X , Y and Z are:

Rank	X	Y	Z
1	A'	B'	C'
2	B'	C'	A'
3	C'	A'	B'

Now considering again individual X in the situation where he knows the various orders of the others (that is, there is full communication, obtained through discussion), he has expected utilities under a wide range of possible actions. For now he has the power to induce an action on the part of another person in response to an action on his part. For example, suppose for him the utility differences between A' , B' , and C' are very small, while the utility differences between A , B , and C are very large. Then he might consider an exchange of votes with Z such that A and C' would win.⁸ His utility under this possible action could

⁷ An incidental point may be made here concerning the apparent reasonableness of the condition of independence of the social ordering of alternatives from the elimination of other alternatives. This appears reasonable, I suggest, because of a too direct analogy between individual rationality and collective rationality. Rather than the concept of collective rationality as a parallel to individual rationality, it is appropriate to look at collective decisions as an outcome of the operation of individual rationality. We can then ask the question: in a given situation and with a given decision rule (that is, including the whole set of actions we are allowing individuals), how closely does the outcome come to maximization of social welfare? This is obviously a more difficult question in collective actions than in individual ones. It will be discussed explicitly later in the paper.

⁸ The one explicit recognition of such vote-exchange behavior by economists is in Buchanan

then be compared with his expected utility under the conditions of no exchange (assuming his subjective probabilities are 1 that Y and Z will vote for B and C respectively):

$$(9) \quad U_{xa} + U_{xc'} \stackrel{?}{>} 1/3 U_{xa} + 1/3 U_{xb} + 1/3 U_{xc} + 1/3 U_{xa'} + 1/3 U_{xb'} + 1/3 U_{xc'}$$

Rearranging,

$$(10) \quad U_{xa} - U_{xb} + U_{xa} - U_{xc} \stackrel{?}{>} U_{xa'} - U_{xc'} + U_{xb'} - U_{xc'}$$

If the indicated utility differences for A , B , and C were greater than the indicated ones for A' , B' , and C' , then he would indeed prefer to make the exchange, rather than not. Similarly, he could consider an exchange with Y , to give outcomes A and B' . If inequality (10) holds, then he will also want to compare the two possible exchanges:

$$U_{xa} + U_{xc'} > U_{xa} + U_{xb'}$$

This inequality does not hold if $U_{xb'} - U_{xc'} > 0$, as the initial order implies. Thus for him the bargain with Y has highest utility. But it may be a bargain which he cannot make, since Y would have to accept the utility of his least preferred alternative, A . That is, $U_{ya} + U_{yb'}$ may not be large enough, compared to the alternative actions, for Y to make this exchange. Considering the possible alternatives for Y as exchanges with X or Z (for in the general case of unequal utility differences between alternatives, some action which involves exchange will always have a higher utility for an individual than an equal chance of all alternatives), there are two cases: B and C' , or B' and C . Thus if either

$$(11) \quad U_{yb} + U_{yc'} > U_{ya} + U_{yb'}$$

or

$$(12) \quad U_{yb'} + U_{yc} > U_{ya} + U_{yb'}$$

then Y will prefer to make an exchange with Z . But Y 's initial preference ordering gives $U_{yc} > U_{ya}$, so that at least (12) will hold. This will not insure, of course, that Z will be satisfied with such a trade.

This kind of behavior need not lead, of course, to a stable solution which, in a game-theoretic sense, dominates all others. The outcome may depend on many chance factors, such as who talks first to whom. However, the basic point is that each person will attempt to maximize

and Tullock [3, Ch. 10]. However, political scientists are so fully aware of this behavior that they have common names for it: "horse-trading," "log-rolling," "making a deal," and other terms that would be appropriate in economic markets.

his expected utility. He will do so by taking that action for which the increment in expected utility—the analog to marginal utility for a situation of this type—is greatest. Ordinarily this action will be one of exchange: increasing his control over a decision for which control makes a great deal of difference in his expected utility, and in return giving up to another person control over a decision for which control makes little difference in his expected utility. If we consider, in the first analysis, his actions to be limited to pairwise exchanges of control, then he will order decisions i in terms of $\Delta U_{xi} = E(U_{xi} | v_{ix}) - E(U_{xi})$, where v_{ix} is an additional vote gained by X on decision i by this action. The relative sizes of ΔU_{xi} for all issues i express his *interest* in gaining a vote on each issue. He will also order possible actions in terms of the decrement in expected utility that the loss of his vote to a given individual k on a given decision j would mean: $\Delta U_{xkj} = E(U_{xj} | v_{jk}) - E(U_{xj})$, where v_{jk} is the transfer of control over his vote on decision j to individual k . Thus, with such a situation and limited to pairwise exchanges, each rational individual will try to carry out an exchange increasing control over decision i in return for losing control over decision j such that ΔU_x is maximized:

$$\Delta U_x^* = \max_{\substack{i,j,k \\ i \neq j}} (\Delta U_{xi} - \Delta U_{xkj})$$

It is useful to consider a particular example of utilities associated with different alternatives which would generate exchange attempts in the case of the above 2-decision system. Assume the following utilities associated with each alternative by each person. (These numbers are to be compared only for a given individual; the scaling for different individuals is arbitrary, since no interpersonal comparison of utility is implied. Also, the full properties of an interval scale are not assumed, but only the "distances" between utilities associated with different alternatives in the same decision. It is more convenient, however, to use specific numbers, even though all the properties of these numbers are not required for the behavior under discussion.)

	X	Y	Z
U_a	10	8	9
U_b	5	10	8
U_c	1	9	10
$U_{a'}$	10	8	9
$U_{b'}$	9	10	6
$U_{c'}$	8	9	10

In this situation gaining control of the first decision clearly has higher expected utility increment for X than does gaining control over the second decision. For if his assessment of the probabilities of A , B , and C is $\frac{1}{3}$ each without control, then if we call ΔU_{x1} his utility increment in decision 1 through gaining control over it,

$$\begin{aligned}\Delta U_{x1} &= U_{xa} - (1/3 U_{xa} + 1/3 U_{xb} + 1/3 U_{xc}), \\ &= 10 - 5.33 = 4.67\end{aligned}$$

and

$$\begin{aligned}\Delta U_{x2} &= U_{xa'} - (1/3 U_{xa'} + 1/3 U_{xb'} + 1/3 U_{xc'}), \\ &= 10 - 9 = 1.0\end{aligned}$$

The loss of utility through giving up his vote to Y or Z can be evaluated as follows, where ΔU_{xy1} is his increment (or decrement) in utility from decision 1 through giving up his vote to Y :

$$\Delta U_{xy1} = 5.0 - 5.33 = -0.33$$

$$\Delta U_{xz1} = 1.0 - 5.33 = -4.33$$

$$\Delta U_{xy2} = 9 - 9 = 0$$

$$\Delta U_{xz2} = 8 - 9 = -1$$

Thus in evaluating the interest of X in particular exchanges (the expected utility of the exchanges) by $\Delta U_{x1} + \Delta U_{xkj}$, two exchanges have sharply higher utility than any others:

$$\Delta U_{x1} + \Delta U_{xy2} = 4.67 - 0 = 4.67$$

$$\Delta U_{x1} + \Delta U_{xz2} = 4.67 - 1 = 3.67$$

A similar evaluation would show that for Y both decisions 1 and 2 are of equal interest, and a trade with Z on either will maximize Y 's expected increment (at 1.0). For Z , control over decision 2 is of most interest, and an exchange with X gives highest expected increment in utility (at 1.67). Thus in this situation, X and Z would make an exchange, giving X control over decision 1 and Z control over decision 2. The outcomes would be A for decision 1, and C' for decision 2.⁹

⁹ If Y was very perceptive, then he would make an offer to Z which would be of higher expected utility to Z (assuming that Z could be sure of Y 's honoring the offer). Y could offer to vote for both C and C' , receiving nothing in return. This would improve his situation over the X - Z coalition, and improve Z 's as well. This in turn would lead to an offer by X to vote for both B and B' , and then to an offer by Z to X to return the original agreement or to vote for A and A' . This possibility of instability, and the various types of possibilities that could occur for other configuration of utilities, need not concern us here—for we are not concerned with the outcome, but with the question of what is rational behavior for the participants. Such behavior depends only on subjective probabilities of others' behavior, together with utilities of various outcomes. In any case, these indeterminacies seem to arise in the few-person case, and our interest is principally in larger systems.

The above discussion should be sufficient to show that when individuals are released from restrictive conditions upon behavior and information (i.e., voting on only one issue and complete absence of information about others' behavior), then rational behavior demands that every alternative which has some subjective probability of occurrence can affect their behavior, though it may be least preferred. As a consequence, when such behavior is allowed, the condition which Arrow states, independence of outcome from "irrelevant" alternatives, can hardly be imposed. For since no alternatives are irrelevant in the expected utility calculations which govern behavior, it is hardly reasonable to expect that any will be irrelevant to the outcome.

Given, then, the freedom from Arrow's impossibility theorem, we can proceed to investigate the structural conditions that will allow expression of more than the simple preferences that voting on a single issue implies.

The principal theoretical approach in the literature makes use of successive adjustments on a single proposal. Knut Wicksell introduced this conception into public finance by asking how taxes could be assessed in such a way that the optimum amount of public services would be provided, and the allocation would be such that marginal benefits equalled marginal costs for each.¹⁰ Wicksell's solution was theoretically most elegant, though it had flaws which made it impossible to carry out in practice. His thesis was: (a) always to vote on a combined proposal which included not only the amount and mode of public expenditure, but also the distribution of taxes or other means of paying for the expenditure; (b) then to require the measure to pass not by majority but by unanimous vote. In this way, the amount of expenditure and distribution of burden would be so adjusted that those who value the activity least would pay least (otherwise they could not be induced to vote for it), and more generally, the amount and distribution would be continually adjusted until each voter's marginal costs equalled his marginal benefits. Such a measure would be approved unanimously, and only such approval, Wicksell held, would assure that benefits were greater than costs for all. Such a principle assumes, of course, that all persons have perfect calculating ability, that there is some means of efficiently carrying out the multiple adjustments in a proposal necessary to reach this state of perfect adjustment, and perhaps most important of all, that people will reveal true preferences. That is, it assumes that all persons are constrained, by fear of retaliation in kind, from understating their interest in the public activity.

However, Wicksell, and all those who have followed in this direction

¹⁰ For Wicksell's contribution see Wicksell [10], and for a discussion of the general approach (including Lindahl's extension of it) see Richard Musgrave [6, pp. 71-80].

(with the exception of Buchanan and Tullock, in *Calculus of Consent*, Chapter 10), limit their attention to the single issue, and limit the resources available to the individual to his vote on this issue. Yet an economic man will be willing to spend various other resources, such as votes on other issues, etc., in proportion to his expected utility gain from their expenditure. Thus if those who are not interested in the decision can extract from the former such resources, down to the last bit that the former are willing to give, the latter will be recompensed, through a much simpler and more efficient mechanism than an attempt to adjust the tax or the expenditures so that it fits perfectly the utility structure of the population. This implies, at the extreme, that it is not important if there are tax loopholes, if these loopholes are made evident to all at time of passage of the bill, and those who will gain from them are made to pay, in terms of other legislation, the full amount that they are willing to pay in order to gain the loopholes.

Thus it becomes fruitful to develop further the possibilities which arise as a consequence of an expanded range of behavior among persons involved in collective decisions—a range of behavior which includes the employment of various resources, especially control over other issues, in the form of votes on other decisions which involve this collectivity. To be sure, such an approach would be academic if the proposed behavior was uncommon or impossible in decision-making bodies. But exactly the contrary is true. Numerous observers of legislative bodies have suggested that the very essence of legislative behavior is exchanges which bring about support on different issues; and there is evidence to suggest that when a single decision dominates a political or social system, so that its importance makes such exchanges impossible, the decision-making process breaks down; and not only is there no “social welfare function,” there is overt conflict. Often, in actual collectivities, such as legislatures, there are a number of other resources that various legislators have, and can use in exchanges. One of these is partial control of positions within the legislature, such as committee membership. All these resources are used in the same way that goods are used in a barter market: in exchange for control over those events whose outcome one is most interested in. Many of these resources act to make unequal the power of different legislators, and thus give unequal degrees of power to their constituents. It is useful to conceive, however, of an ideal simple collectivity in which each actor’s only resources are his votes on other collective decisions. With such a conception, one can raise the question of what conditions would allow the system of exchange to approach more nearly the free markets which in pure economic competition allow individuals to maximize their utility, relative to their initial resources.

II. *Extensions to Many Decisions and Many Individuals*

From the three-person, two-decision example above, two kinds of extensions are possible, affecting the result in different ways. One is an extension to a greater number of decisions, and the other is an extension to a greater number of individuals. I shall consider first the former.

In this example, it was worth a great deal, in *X*'s private utility calculations, to gain alternative *A* rather than *B*; and worth still more to gain *A* rather than *C*. In contrast, it was worth little to *Y*, relative to his other utility comparisons, to gain *B* rather than *C*, or *C* rather than *A*. Yet for the very small gain of *C* in place of *A*, *Y* could make an offer to *Z* which might overcome *X*'s potential agreement with *Z*. For a gain to *Y* that was a smaller gain than several others for him, he could counter an agreement of *X*'s which would make most difference to *X* of all possible agreements. Thus even though this agreement was of utmost importance to *X*, he had no way of implementing his feelings, though it would obviously be worth more to him relative to his other interests to gain control of this decision than to either *Y* or *Z* (again, relative to *Y*'s and *Z*'s other interests).¹¹

An extension in number of decisions destroys this inequity, by giving each of the persons a large amount of resources which he can employ or fail to employ on a decision, depending on its importance to him. For example, assume that there were a hundred other issues, each with three alternatives, *A*, *B*, *C*, and each ranked as in the first decision by *X*, *Y*, and *Z*. Suppose also that the relative utilities were in each case except the first, 10, 9, and 8, for each of the three members. Then individual *X*, to whom the first decision is of such importance, could offer to *Z* enough to express this importance. He could, for example, offer *Z* his vote on decisions 2 and 3, an offer which would be impossible for *Y* to counter and still make an expected profit, but one which would still leave *X* with an expected gain on these decisions considered all together.

More generally, the extension from two decisions to a great many allows even more flexibility of adjustments in exchange than this example indicates. In the extreme case, it approaches in one sense a market situation, in which persons have various resources, divisible into small units, and also many different wants. Each person's wants, of course, are scaled by the totality of his resources; but he can pay out various quantities of resources in order to get those things he wants

¹¹ Note that this is still a step away from interpersonal comparison of utility, since each's interests in a particular action are assessed only relative to his other interests. Although this paper will not examine the question in detail, the logic contained here implies that the only basis for an interpersonal comparison is a scaling of his interests by the resources he has in the system—that is, by the degree of control over various events given to him by the constitution of the collectivity.

most. In terms of political preferences, this means that those decisions for which the alternatives differ most for him in utility are the ones over which he can gain control through giving up his partial control over those of less importance to him. It allows, in short, an expression of "intensity" such that the outcome of the decision will tend to be the one which maximizes aggregate utility.¹²

This extension from a few decisions to a great many leads toward a market in one way, but not in another. With a very small number of persons, there can still be a large difference between the "price" paid for a vote (in terms of other votes) and its value to the purchaser. If the decisions that are of great interest to him are of little to the other persons, he can gain control over them with little sacrifice on his part, and then tend to gain more in utility from the set of decisions than his power would warrant. He, in effect, would be in the role of monopolist, who can drive the price down to what he is willing to pay.

An extension in the direction of a great number of other individuals engaged in the set of decisions moves this in the direction of a free market, in which prices are established by competition among both buyer and seller.

A large and complex society, where there is a complex web of interdependence among various activities, tends to generate both the extensions discussed here. The extension of decisions occurs simply through the extension in time of the society; the extension in number and utility-variations of individuals occurs through the complexity of the economic and social structure. It is true, of course, that the particular form of government distributes power over particular decisions in special ways, which may neglect the interests of some persons and give great weight to the interests of others. But that is a matter which can be more fully studied when the fundamental points discussed in this paper are better understood. The major point to be made here is that, just as a free market with pure competition can be conceived in economic exchange, and used as a theoretical model from which actual systems can be examined, a similar model of pure competition can be conceived in collective decisions. Although actual social systems deviate from this model, it can nevertheless serve as a basis from which the deviations can be studied.

III. *An Ideal System of Collective Decisions*

The system of collective decisions differs in several important respects from economic markets. One respect, which we shall not investigate, is that occasioned by time: collective decisions are made in a sequence,

¹² It must be clearly understood that the aggregating function is one in which the sum of each person's utility differences between outcomes over all decisions are weighted by his power over the decisions. Thus the total sum of each person's utilities as used in aggregating is proportional to the sum of his power. The precise definition of this power is given later in the paper.

over an extended period of time, while in some economic markets, time need not be taken into account. Though time, together with discounting, mechanisms of credit-extension, insurance, etc., must play an important part in the further development of the present theory, the elements will be left unexamined here.

Another way in which this case differs from economic markets is in the lesser flexibility in exchange—for example, the relative absence of successive exchange of the same goods. Since the entities being exchanged are promises of an action, these promises are not as negotiable as economic goods, or money by which such goods are counted. Another aspect of the lack of flexibility is the fact that in this case, power leads to realization of interests; but the interest gained cannot be reconverted to power in the same way that economic goods, once gained, can be reconverted in a perfect market to the money which bought them. As a consequence of this last point, and of the lack of a measure of value such as money, it is necessary to devise a different way to express the value of power over a particular issue. The equation to be presented below is consistent with the framework of economic markets, but it is applicable in collective decisions as well, which do not generate their own measure of value.

Let us first define a quantity which is analogous to ΔU_{xi} above, which was the interest of X in gaining a vote on decision i . It was defined as the difference in expected utility due to that vote. Now, let us define analogously r_{ix} as the difference in expected utility given that the decision is under his control (which is merely the utility of the most-preferred alternative), and the unconditional expected utility:

$$(13) \quad r_{ix} = U_{xi} - E(U_{xi})$$

where A is the alternative most preferred by X in decision i . This we will call, for heuristic purposes, X 's *interest* in the decision. This is assumed to be exogenously given, dependent on the structure of social and economic activities, and the content of decision i .

Also exogenously given is the formal control structure over the issue. In the case of m decisions decided by a vote among n individuals, each person has control of $1/n$ on each of the m decisions. This will be labelled c_{ij} , the control of individual j over issue i . The total resources of individual j consist of his control over all issues, but weighted by the value or "importance" of each decision. If the value of each decision is v_i , then the power of individual j is

$$p_j = \sum_{i=1}^m v_i c_{ij}$$

where

$$\sum_{j=1}^n c_{ij} = 1.$$

The total control over each decision is 1, that is, $\sum_{j=1}^m c_{ij} = 1$. Now given these definitions, the value of a given decision where there is pure competition is the sum of each actor's interests times the power of that actor:

$$(14) \quad v_i = \sum_{j=1}^n r_{ij} p_j,$$

or

$$(15) \quad v_i = \sum_{j=1}^n \sum_{k=1}^m r_{ij} v_k c_{kj}.$$

This recursive definition says in effect that the value of a decision is equal to the sum of the interests of each individual in the decision, but weighted by the power of the individual. In turn, the individual's power depends upon the value of those issues over which he has some control.

Solution of equation (15) for the set of v_i can give the value or price which any individual should have to pay to gain control over each decision.¹³ Such prices would not be exact in imperfect competition, but where there are enough competitors and enough decisions, the price should come to that point. This gives both the value of an individual's resources (i.e., votes) in the market, and the price he can expect to pay for decisions he wants. It establishes the rate of exchange which should obtain as the market approaches rationality.

IV. *More Fundamental Revision*

In a sense, the above discussion has gone at the problem backwards, showing how a framework of exchange in a free market is possible in collective decisions just as in the exchange of economic goods. This is necessary for historical reasons. But having done so, it is more profitable to attempt to restate the general theory in a way that is appropriate to collective decisions and then show that exchange of private goods is a degenerate case. The basic elements of such a theory will be indicated below, but only to show the way in which such a generalization could proceed.

Consider the world as consisting of a set of *events*. Each event has two or more possible outcomes, and these outcomes have consequences for individuals, which the individuals evaluate differentially. Each event is also characterized by a distribution of control over the outcomes. The sum of such control is less than or equal to 1.0, and it may be conceived

¹³ In solving this set of equations for v_i , it should be noted that the row constraint on c_{ij} means that there are only $m-1$ independent v_i 's. That is, the values are determined only relative to some arbitrary sum, say

$$\sum_{i=1}^m v_i = m.$$

as the probability that the person holding the control can determine the outcome.

Then in a market of exchange of economic goods, the goods themselves are the events. Consumption of the good by a given individual is one outcome of the event. Possession of the good constitutes control over the event. Thus this is a simple situation in which the consequences of a given outcome are zero for all individuals other than the individual who consumes it, and control over the event is always 1.0 for the person in whose possession the goods lie, and 0 for all others.

The fact that makes some events come under multiple control in collective decisions is their multiple consequences, or "externalities." Whatever outcome is chosen, it will have consequences for many individuals. Thus many have an interest in gaining control of it, and various forces (in *other* collective decisions) move such events into the area of collective decisions, with a certain structure of control (such as one vote for one person). Thus collective decisions are events in which control is formally distributed over more than one actor (though it may come into the hands of a single actor, through exchanges). They tend also to be events in which any outcome has consequences for many actors. Because of the divided control, a much more extensive calculation—using expected utility, rather than certain utility—is necessary in carrying out rational behavior. Nevertheless, the structure is the same, and the private-goods exchange case can be treated as a special case in which the control over an event is always 0 or 1. The equations of exchange in the collective decision case should thus reduce to those of the private goods case when the matrix of control takes on a special form.

V. Conclusion

One might be tempted to develop these ideas further in a game theoretic direction, since obviously game theoretic considerations are relevant. One referee has suggested that the points developed above are more relevant to game theoretic analysis of political behavior than to Arrow's and subsequent work on a social welfare function. This, however, misses the major import of the paper. Arrow's work, by attempting to derive social choice as a function of individual preference, begins to shift the idea of a social welfare function away from a normative concept to a positive one. I. M. D. Little and others of a normative persuasion have recognized this danger and rejected Arrow's approach as irrelevant to welfare economics. Having begun the shift, however, one cannot stop halfway, but must incorporate in the theory that behavior which the rational actor would carry out. Arrow's theorem depends upon individual rationality under certainty, which allows no expres-

sion of intensity of preference, but only ordering among alternative outcomes. It is clear, however, first, that rational behavior in collective decisions requires rationality under uncertainty or risk, which opens the possibility of expression of intensity of preference; and second, that in actual groups, the existence of a sequence of decisions gives actors the resources that allow the expression of such intensity, even if imperfectly and incompletely.

When one takes this perspective, political behavior can be viewed as a generalization of market behavior, and the functioning of legislatures or other bodies in collective decisions as an extension of a market. In this "market," each actor has only partial control over any given outcome, rather than complete control over a goal, thus requiring the more complex calculations of rational behavior under risk. This extension of rationality has been developed as part of game theory; but to categorize the present results as work in game theory trivializes them by limiting their use to micro-systems, in which game-theoretic solutions can be calculated. It would be as if the indeterminacy of outcome in a two-person bargaining situation had constrained economists from developing the concept of a perfect market, and the power that brings to economic analysis.

Similarly, in collective decisions, disregarding the confusion and indeterminacy of game-theoretic solutions in a micro-system (for small-number interaction cases are always the most difficult for analysis), one can develop an idea of a perfect system of collective decisions, and thereby derive the value of control over a given decision, and the power of a given actor, and can ultimately develop for such decisions the tools of economic analysis.

A RESTATEMENT OF THE QUANTITY THEORY OF MONEY

By MAURICE ALLAIS*

Up to 1950, there was no attempt to derive a formulation of the demand for money. The Newcomb-Fisher equation of exchange, Walras' formulation, and those of the writers of the Cambridge School—Marshall, Pigou, and Keynes—have had little value other than as purely formal frameworks for the description of the facts.¹ A new formulation which has an operational and general significance is proposed in this paper: the hereditary, relativistic, and logistic formulation of the demand for money. The significance of this formulation can be fully appreciated only by considering it against the background of the results which were obtained some ten years earlier.

I. Earlier Results

During 1953–54, Cagan [10] and Allais [3], both working independently of each other, tried to find an operational formulation of the quantity theory. They both reached the same formulation, although their starting point presentation and terminology were different.^{2,3} This formulation was:

$$\begin{array}{ll}
 (1.1) \left\{ \begin{array}{l} (a) \frac{M}{P} = \phi(u) = \phi_0 e^{-Ku} \quad (\text{Cagan}) \\ (b) \frac{M}{D} = \phi(u) = \phi_0(1 - Ku) \quad (\text{Allais 1954}) \end{array} \right. \\
 (1.2) \left\{ \begin{array}{l} (a) \frac{du}{dt} = \bar{x}(x - u) \\ (b) u = \frac{\int_{-\infty}^t x(\theta) e^{-\bar{x}(t-\theta)} d\theta}{\int_{-\infty}^t e^{-\bar{x}(t-\theta)} d\theta} \end{array} \right. \\
 (1.3) \left\{ \begin{array}{l} (a) x = \frac{1}{P} \frac{dP}{dt} \quad (\text{Cagan}) \\ (b) x = \frac{1}{D} \frac{dD}{dt} = \frac{1}{P} \frac{dP}{dt} + \frac{1}{Q} \frac{dQ}{dt} \quad (\text{Allais}) \end{array} \right.
 \end{array}$$

* The author is professor of general economics, Ecole Nationale Supérieure des Mines; professor of theoretical economics, Statistical Institute of the University of Paris and research director, French National Center for Scientific Research.

¹ For an account of the historical development of the quantity theory see [8, pp. 27–39 and 153–54].

² For clarity, Cagan's formulation is given here in the notation used in this paper. The correspondence between the notations is as follows:

Cagan (1954)	C	E	α	β	$e^{-\tau}$
Allais (1954)	x	u	K	\bar{x}	ϕ_0

³ As far as I am aware, the formulation (1.2a) was suggested to Cagan by Milton Friedman, who later used it in his theory of permanent income [12, pp. 142–45]. Cagan's research was brought to my attention by Friedman in a discussion we had in July 1954 when I described to him the interesting results I had reached using the formulation (1.2b) in my research on the theory of the business cycle [3].

where D is total outlay, P the price level, Q the activity index, and ϕ_0 , K , and \bar{x} are constants. Total outlay D can be considered, at least as a first approximation, proportional to national income R at current prices, a property which is expressed by the relation

$$(1.4) \quad \frac{D}{R} = \text{a constant.}$$

For hyperinflations, it is approximately true that

$$(1.5) \quad \frac{D}{P} = \text{a constant.}$$

If the case of hyperinflation is excluded, u is small and

$$(1.6) \quad e^{-Ku} \approx 1 - Ku.$$

It follows from this that the formulations (1.1) employed by Cagan and Allais were not only the same, but they also applied in the same way to concrete economic data. Allais called the quantity u the psychological rate of expansion; Cagan called it the coefficient of expectation. Cagan laid most stress on the differential equation (1.2a); Allais on the equivalent integrated expression (1.2b). For Cagan, future expectations were the important factor; for Allais, the memory of past events; but these were only two facets of one and the same mathematical formulation. For both Cagan and Allais, the only way to calculate the coefficient u was to consider the approximation

$$(1.7) \quad u_n = \frac{\bar{x}_n + k\bar{x}_{n-1} + \dots + k^p\bar{x}_{n-p} + \dots}{1 + k + \dots + k^p + \dots}$$

with

$$(1.8) \quad \bar{x}_n = \frac{1}{p} [l_n D_n - l_n D_{n-1}]^4$$

where p is the length of the interval of elementary time considered, with

$$(1.9) \quad k = e^{-p\bar{x}}.$$

Relation (1-7) indicates that the coefficient u is merely the weighted average of earlier rates of growth of total outlay, with weighting coefficients which decline exponentially with distance in time. For Allais, however, this formulation was merely one component of a more general theory of monetary dynamics based on the relation

⁴ The notation \ln represents the natural logarithm.

$$(1.10) \quad \frac{dD}{dt} = \lambda[M - M_D]$$

where λ is a constant and M_D the desired cash balances. But because the difference $M - M_D$ is always small, Allais could determine the function ϕ statistically by taking the ratio M/D and assuming

$$(1.11) \quad M_D \approx M.$$

Cagan's formulation assumed implicitly that

$$(1.12) \quad M = M_D.$$

Overall, both authors followed the Walras-Cambridge school formulation. The terminology employed by Allais places him in the Walrasian line of thought, whereas Cagan's terminology is in the tradition of the Cambridge school. Fundamentally, however, since Allais considered the ratio

$$(1.13) \quad \frac{M}{D} = \frac{M}{PQ},$$

his formulation was that of the Cambridge school, whereas Cagan, considering the ratio M/P , was using the Walrasian formulation. Leaving aside differences in terminology, the coefficient used by both authors was the weighted average of earlier rates of growth of total outlay, with weighting coefficients declining exponentially with distance in time.

Overall, the results obtained by Cagan in 1954 were excellent, while Allais' results (1954) for France and the United States were quite remarkable, and in general provided a satisfactory fit of the data. The only significant exception was the period 1820-1870 for France, but the figures used for money in circulation and national income were highly questionable. However, Cagan had only succeeded with his formulation in representing the central period of the hyperinflations studied. It was still beyond the power of his formulation to deal satisfactorily with the beginning and terminal stages. Furthermore, he had been no more successful than Allais in finding a single formulation capable of dealing with all the cases studied.⁶ The main results reached by the Allais (1954) and Cagan (1954) formulations are presented in Table 1.

The values found for \bar{x} and K are *very different*, and the different laws cannot be brought into any consistent relationship with each other. But two remarks may be made: (1) the values of the product $K\bar{x}$ are remarkably steady and are all in the neighborhood of 0.75; (2) the rate of forgetfulness \bar{x} is the greater, and the coefficient K the smaller, the higher

⁶ Cagan [10, pp. 43-46 and 55-57].

the average value \bar{u} of the rate of expansion during the period considered. Further, since the value of relative desired cash balances ϕ is the smaller the higher the value of u , it may be said that the coefficient of forgetfulness is the higher the lower the value of relative desired cash balances, or the greater the velocity of circulation.⁶

II. *The Hereditary, Relativistic, and Logistic Formulation of the Demand for Money*

A. *The H.R.L. Formulation*

The H.R.L. formulation of the demand for money, the fruit of fifteen years of research,⁷ is based essentially on the following three ideas.

1. Monetary theory requires a formulation based on a general theory which can bring all monetary phenomena into the same logical framework, whether they relate to equilibrium situations, to cyclical fluctuations, or to hyperinflations.

2. At any given moment, the relative demand for money—in other words, the demand for money in relation to the national income—depends only on the historical development of the nominal value of national income. There is thus a “hereditary” effect, with the influence of past events becoming attenuated as they fall farther back in time.

3. Provided that a psychological time scale is considered such that the rate of forgetfulness per unit of time is constant, the “hereditary” expression of the demand for money is the same at all places and times.

The postulates of the H.R.L. formulation were derived from the results of the previous researches only after a long prior analysis.⁸ This paper is limited to their enunciation, and the deduction of the consequences flowing from them.

B. *Relativistic Postulate (Postulate I)*

In relation to physical time, it is assumed that an instantaneous coefficient of forgetfulness, $\chi(t)$, can be defined such that the effect of attrition of the memory of past events between τ and t can be represented by the coefficient

$$(2.1) \quad \exp - \int_{\tau}^t \chi(u) du$$

which has an exponential form. A psychological time scale t' can then

⁶ For more details see [8, pp. 159–80].

⁷ Allais [1] to [8].

⁸ The starting point of the formulation below was my books *Economie et intérêt* [1] and *Les fondements comptables de la macro-économique* [4] and the research which I undertook between 1952 and 1955, which is described in three successive papers [2] [3] [5]; for more details see [6] [8] [9].

be defined such that

$$(2.2) \quad \chi(t)dt = \chi'dt'$$

where χ' is a constant; i.e., when measured in relation to psychological time, forgetfulness per unit of time is constant. In other words, by reference to this psychological time scale, memory is invariant.⁹

This leads to the relation

$$(2.3) \quad t' = h(t)$$

linking psychological and physical time.

Writing $D(t)$ for total outlay per unit of physical time by all economic agents,

$$(2.4) \quad \begin{aligned} D(t) &= \sum_i p_i(t)q_i(t) \\ &= P(t)Q(t) \end{aligned}$$

where p_i and q_i represent the price and volume of the various basic transactions i , and where P and Q are appropriate indices of price and of economic activity. When referred to the psychological time scale, total outlay per unit of time is $D'(t')$, whence

$$(2.5) \quad D'(t')dt' = D(t)dt.$$

However, it is assumed that the macroeconomic quantity taken into consideration by economic agents in the process of monetary decision-making is total outlay $D(t)$, whatever the time-scale referred to. In other words, it is assumed that $D(t)$ is an invariant psychological datum, independent of any time-scale reference.¹⁰ This hypothesis was initially developed on the basis of psychological considerations, and its retention is attributable to the success of its application in the analysis of the empirical series.

When expressed in terms of the psychological time scale, the rate

$$(2.6) \quad x'(t') = \frac{1}{D(t')} \frac{dD(t')}{dt'}$$

will be referred to as the instantaneous rate of increase of total outlay. Where physical time units are employed, this rate is given as¹¹

$$(2.7) \quad x(t) = \frac{1}{D(t)} \frac{dD(t)}{dt}$$

⁹ This assumption had already been formulated in my 1955 paper [5, §26, pp. 273-74, relation 48].

¹⁰ See note (11) below.

and of course, from (2.6) and (2.7)

$$(2.8) \quad x' dt' = x dt.$$

The first postulate thus signifies that there exists a psychological time t' which differs from physical time t . Measured against this psychological time scale, the rate of forgetfulness per unit of time is assumed to be independent of the period under consideration. This condition defines psychological time. Furthermore, the quantity of money M and total outlay per unit of physical time $D(t)$, are taken to be accepted by economic agents as invariant psychological data, independent of the time scale used for reference.¹²

C. Hereditary Postulate (Postulate II)

Decisions by economic agents are assumed to be taken in relation to past changes in total outlay, represented by an index which is termed "the rate of psychological expansion." In relation to the psychological time scale, the "psychological rate of expansion" is assumed to be a weighted average of all preceding rates of expansion and is defined by the relation

$$(2.9) \quad z' = \frac{\int_{-\infty}^{t'} x'(\tau') e^{-\chi'(t'-\tau')} d\tau'}{\int_{-\infty}^{t'} e^{-\chi'(t'-\tau')} d\tau'}$$

where χ' is a constant. This relation specifies the "hereditary" nature of the link that exists between the psychological rate $z'(t')$ and the instantaneous rates $x'(\tau')$.¹³ The weighting coefficients

$$e^{-\chi'(t'-\tau')}$$

decline exponentially with time when referred to the psychological time scale. It follows from relation (2.9) that

$$(2.10) \quad \frac{dz'}{dt'} = \chi' [x' - z'].$$

¹² And *not*, it cannot be too strongly stressed

$$x'(t') = \frac{1}{D'(t)} \frac{dD'(t)}{dt'}.$$

To consider D and not D' means that psychologically it is D which constitutes an invariant concept from the point of view of appreciation of the economic situation. On this point see [8, pp. 80-81].

¹³ On relativistic effects in the social sciences, see [8, pp. 23-25].

¹⁴ On hereditary effects in the social sciences, see [8, pp. 21-22].

Postulate II is thus equivalent to the assumption that the formulation (1.2) used by Cagan and Allais in 1954 is valid, but that it is valid only when considered in relation to the psychological time scale. The parameter z' is therefore a magnitude which may be compared with the parameter u of Section I. Similarly χ' is comparable to the coefficient $\bar{\chi}$ of that section.

Using the definition of z in the physical time scale

$$(2.11) \quad z(t) = z'(t');$$

then from the relation (2.3) and (2.8), and using physical time, we have

$$(2.12) \quad \frac{dz}{dt} = \chi' \left[x - \frac{x}{\chi'} z \right].$$

The behavior of economic agents insofar as their desire to hold money is concerned can be measured by

$$(2.13) \quad \phi_D = \frac{M_D}{D},$$

i.e., by the ratio between desired money balances M_D and total outlay per unit of physical time, D . This ratio is referred to throughout as "relative desired money balances"; it can also be designated as the relative demand for money.¹⁴ It is assumed that relative desired money balances ϕ_D are a function of z :

$$(2.14) \quad \phi_D = \phi(z).$$

Thus, Postulate II signifies that the monetary behavior of economic operators, when referred to a psychological time scale, is a function of a psychological rate of expansion. This rate is found as the weighted average of the instantaneous rates of increase x' of total outlay D , measured against the psychological time scale, with the weighting coefficients declining exponentially with the passage of time, and the coefficient of forgetfulness χ' being constant.

D. The Postulate of Invariance of the Function of Relative Desired Money Balances When Referred to the Psychological Time Scale (Postulate III)

The constant ϕ_0 and the function $\phi(z)$ are defined by the relation

$$(2.15) \quad \phi_0 = \phi_D(0)^{15}$$

¹⁴ In earlier papers, [1] to [7], I used the term "real value of wanted cash balances," but this suggested that ϕ_D was derived by dividing M by P , whereas in fact it is the quotient resulting from division by the product PQ . This was a possible source of confusion and I have altered the terminology.

¹⁵ It follows from this that ϕ_0 is not the initial value of ϕ , but the value of ϕ for $z=0$.

and

$$(2.16) \quad \varphi(z) = \frac{\phi(z)}{\phi_0}.$$

It is assumed that φ is an invariant function of z , i.e., that it is independent both of circumstances and of the institutional framework. This function is designated as the "function of desired money balances."

Thus, Postulate II signifies that, subject to application of a given coefficient, relative desired money balances are a function of the psychological rate of expansion which is independent of time and place.

E. The Postulate of a Constant Velocity of Circulation of Desired Money Balances when Referred to a Psychological Time Scale (Postulate IV)

When related to a psychological time scale, the velocity of circulation V'_D of desired money balances can be defined by the relation

$$(2.17) \quad D' = M_D V_D'^{16}$$

where D' represents total outlay per unit of psychological time. It is assumed that, as for the coefficient of forgetfulness χ' , the velocity V' is constant.

When the physical time-scale is referred to, we have

$$(2.18) \quad D = M_D V_D$$

where V_D is the velocity of circulation of desired money balances M_D measured in relation to physical time, and from (2.13)

$$(2.19) \quad V_D = \frac{1}{\phi_D}.$$

The velocity of circulation of desired money balances thus appears as the reciprocal of relative desired money balances. From relations (2.2), (2.5), (2.14), (2.17), (2.18) and (2.19), we have

$$(2.20) \quad \frac{\chi}{\chi'} = \frac{1}{V'_D} \frac{1}{\phi(z)}.$$

The instantaneous coefficient of forgetfulness χ thus appears as a function of z . We see that the coefficient of forgetfulness is inversely proportional to the level of relative desired money balances.

Postulate IV thus signifies that the velocity of circulation of desired

¹⁶ M_D is invariant, i.e.

$$M'_D = M_D$$

where M'_D represents the value of desired money balances with reference to the psychological time scale.

money balances, when referred to a psychological time scale, is assumed to be a constant, independent of time. It follows from this and the preceding postulates that the rate of forgetfulness is inversely proportional to relative desired money balances, i.e., proportional to the velocity of circulation of desired cash balances.

It is natural to assume that for

$$(2.21) \quad z = z' = 0$$

the instantaneous scale of psychological time is identical to the physical time scale. This implies that

$$(2.22) \quad x_0 = \chi(z = 0) = \chi'.^{17}$$

From (2.14), (2.15) and (2.20)

$$(2.23) \quad x_0 = \frac{\chi'}{V'_D} \frac{1}{\phi_0}$$

i.e., from (2.22)

$$(2.24) \quad V'_D = \frac{1}{\phi_0}$$

so that from (2.20)

$$(2.25) \quad \frac{\chi}{\chi'} = \frac{\phi_0}{\phi(z)}$$

and also, from (2.16)

$$(2.26) \quad \frac{\chi}{\chi'} = \frac{1}{\varphi(z)}$$

and whence, from (2.12) and (2.22)

$$(2.27) \quad \frac{dz}{dt} = x_0 \left[x - \frac{z}{\varphi(z)} \right].$$

F. The Hereditary Relativistic Formulation

To facilitate the econometric analysis, it is advantageous to consider the index Z defined by the relation

$$(2.28) \quad Z(t) = \frac{z(t)}{x_0}.$$

¹⁷ It follows from this assumption that in a stationary process in which total outlay D is constant, the psychological time scale is identical to the physical time scale. In this case, $x(t) = 0$, so that $z(t) = 0$, whence $\chi = \chi_0$ and, from (2.2), $dt = dt'$.

Z has no dimension with reference to time, and it can for this reason be denoted as the "intrinsic psychological rate of expansion." Putting

$$(2.29) \quad \varphi(z) \equiv \psi(Z)$$

from the set of Postulates I, II, III, and IV, we can write (relations 2.13, 2.14, 2.16, 2.29, 2.27, and 2.28)

$$(2.30) \quad \phi_D = \frac{M_D}{D}$$

$$(2.31) \quad \frac{\phi_D}{\phi_0} = \psi(Z)$$

$$(2.32) \quad \frac{dZ}{dt} = x - \frac{x_0 Z}{\psi(Z)}$$

where ψ is a determinate function of Z .

This formulation can be thought of as being hereditary and relativistic; hereditary because of relation (2.9), relativistic because of relation (2.2). For simplicity, it may be designated as the "H.R. formulation." In fact, this formulation leads to the following assumptions: (a) that the velocity of circulation of desired money balances

$$(2.33) \quad V_D(t) = \frac{D(t)}{M_D(t)}$$

is a function of time only through the intermediary agency of the psychological rate of expansion $Z(t)$, which summarizes the past history of the rate of growth $x(t)$ of nominal total outlay;¹⁸ and (b) that if the time scale is modified in such a way as to render the instantaneous rates of forgetfulness constant—in other words if the the passage of time is so regulated that the memory of past events fades at a constant rate—the velocity of circulation of desired money balances is constant when measured against this new reference scale. This is equivalent to assuming that in physical time the velocity of circulation of desired money balances $V_D(t)$ is proportional to the instantaneous rate of forgetfulness $\chi(t)$. The H.R. formulation does not determine the function $\psi(Z)$; this can only be done by the introduction of further postulates.¹⁹

G. The Logistic Postulate (Postulate V)

The following postulate has been derived by inductive reasoning: The relative change in relative desired money balances is proportional

¹⁸ Relations (2.9), (2.11), and (2.28).

¹⁹ M and M_D of course are quantities without any time dimension. $D(t)$, $\chi(t)$, $x(t)$, $z(t)$, and $V_D(t)$ are quantities whose dimension is inverted time. $\phi(t)$ and $\varphi(t)$ have a time dimension.

CHART 1.

to the change in the psychological rate of expansion, the coefficient of proportionality being proportional to the relative gap between relative desired money balances and their maximum, which is assumed to be finite.

This property is translated by the relation

$$(2.34) \quad \frac{1}{\psi} \frac{d\psi}{dt} = -\alpha \frac{\psi_M - \psi}{\psi_M} \frac{dZ^{20}}{dt}$$

in which ψ_M designates the maximum value of ψ , whence, by integration,

$$(2.35) \quad \psi(Z) = \frac{1+b}{1+be^{\alpha Z}}$$

where α and b are two constants and

$$(2.36) \quad \psi_M = 1+b.$$

Postulate V thus signifies that the function ψ is a logistic function of Z . The shape of the curve of the function $\psi(Z)$ is shown in Chart 1.

H. H.R.L. Formulation

From relations (2.29), (2.30), (2.35), (2.9), (2.11), (2.8), (2.2), (2.28), (2.26), and (2.22), the hereditary, relativistic, and logistic formulation,

²⁰ The assumption of proportionality of $(1/\psi)(d\psi/dt)$ and dZ/dt is quite natural, but if ψ is assumed to have ψ_M as a maximum value, the coefficient of proportionality should cancel out for $\psi = \psi_M$. The simplest assumption, then, is to assume that the coefficient of proportionality is linear in ψ .

which may for brevity be referred to as the H.R.L. formulation, and which follows from Postulates I to V, is summarized by the following relationships:

$$(2.37) \quad \phi_D = \frac{M_D}{D}$$

$$(2.38) \quad \frac{\phi_D}{\phi_0} = \psi(Z)$$

$$(2.39) \quad \psi(Z) = \frac{1+b}{1+be^{\alpha Z}}$$

$$(2.40) \quad Z(t) = \int_{-\infty}^t x(\tau) \exp \left[- \int_{\tau}^t \chi(u) du \right] d\tau$$

$$(2.41) \quad \frac{\chi}{\chi_0} = \frac{1}{\psi(Z)}$$

or, in differential form²¹

$$(2.42) \quad \frac{1}{\psi} \frac{d\psi}{dZ} = -\alpha \left[1 - \frac{\psi}{1+b} \right]$$

$$(2.43) \quad \frac{dZ}{dt} = x - \frac{\chi_0}{\psi(Z)} Z$$

The parameters α and b have no dimension. They specify the form of the function $\psi(Z)$. The coefficient χ_0 specifies the rate of forgetfulness of past events when the value of Z is zero.

I. Postulates Concerning the Constants

The constants α , b , and χ_0 of the H.R.L. formulation can be determined from three postulates: the asymptotic postulate, the postulate of conjunctural symmetry,²² and the postulate of temporal symmetry.

The Asymptotic Postulate (Postulate VI) When the relative demand for money is very small, so that changes of its square can be neglected, although the changes themselves are not necessarily negligible, the rate of psychological expansion is equivalent to the rate of increase of the circulation of money referred to the psychological time scale. Mathematically, this postulate can be written

²¹ Relations (2.34) and (2.32).

²² In French "Postulat de symétrie conjoncturelle." In French, the phrase "appreciation de la conjoncture" relates to the assessment of the economic situation and its development taking both terms in a broad sense.

$$(2.44) \quad z = \frac{1}{M_D} \frac{dM_D}{dt} \rightarrow 0 \quad \text{when} \quad \psi \rightarrow 0 \quad \text{and} \quad \frac{d\psi^2}{dt} \rightarrow 0$$

even if $\frac{d\psi}{dt}$ does not tend to zero.

In this case, it can be shown that it follows necessarily that

$$(2.45) \quad \alpha = 1.$$

It can in fact be shown that the H.R.L. formulation implies²³

$$(2.46) \quad \frac{1}{M_D} \frac{dM_D}{dt'} - z = \frac{\left(1 - \alpha + \frac{\psi b}{1 + b}\right)}{\alpha \left(1 - \frac{\psi}{1 + b}\right)} \frac{d\psi}{dt},$$

whence it follows immediately that Postulate VI implies (2.45).

The significance of this postulate becomes clear if it is assumed that (as experience confirms) the difference $(M - M_D)$ always remains relatively small,²⁴ i.e., that in practice

$$(2.47) \quad \frac{1}{M_D} \frac{dM_D}{dt'} \approx \frac{1}{M} \frac{dM}{dt'}.$$

The practical interpretation of Postulate VI is that at the end of a hyperinflation the psychological rate of monetary expansion z is equivalent to the rate of growth of the supply of money referred to the psychological time scale, which appears to be a quite reasonable property to assume.

It is interesting to note that from (2.46) this property is always valid whatever α if the assumption is made that $d\psi/dt$ tends to zero at the same time as ψ . But in point of fact, for none of the hyperinflations to date is it possible to consider $d\psi/dt$ as negligible by comparison with the rate $z = \chi_0 Z$.²⁵

The Postulate of Psychological Conjunctural Symmetry (Postulate VII). Starting from stability ($Z=0$), the intensity of the differential behavior of the economic agents is assumed to be the same, whether expansion or recession is in progress. This condition implies that the derivative $d\psi/dZ$ of relative desired money balances with respect to Z is a paired function of Z in the neighborhood of $Z=0$. It can then be deduced immediately that

²³ Relations (2.2), (2.6), (2.10), (2.11), (2.13), (2.16), (2.29), and (2.42). See [8, pp. 82-84].

²⁴ See below, condition (3.1).

²⁵ As will be seen from the fittings obtained.

$$(2.48) \quad b = 1.$$

The Postulate of Psychological Temporal Symmetry (Postulate VIII). Economic agents are assumed to take the past into consideration as they do the future. This postulate implies that

$$(2.49) \quad x = i$$

where i is the pure rate of interest.

It follows that

$$x_0 = i_0 \quad \text{for} \quad Z = 0.$$

For the period 1880–1956, the pure rate of interest i_0 can be taken as having been 5 per cent per annum in the United States, for which country satisfactory estimates are available.²⁶ Thus we can take

$$i_0 \approx 0.004 \text{ per month}$$

so that for all countries for which the rate i_0 can be considered as practically equal to its value in the United States

$$(2.50) \quad x_0 = 0.004$$

where the time unit is the month.

J. *The Hereditary, Relativistic and Logistic Law* ($\alpha = 1$, $b = 1$, $x_0 = 0.004$)

In sum, the following formulation follows from the eight postulates which have been given earlier:²⁷

$$(2.51) \quad \psi(Z) = \frac{2}{1 + e^Z}$$

$$(2.52) \quad \frac{dZ}{dt} = x - 0.002(1 + e^Z)Z.$$

This formulation follows from principles which are, from both an economic and psychological standpoint, extremely simple and quite appealing.

III. *The Confrontation of the Theory and Empirical Data*

A. *Money Balances Desired and Held*

"Desired Money Balances" M_D is a psychological concept and of course no statistical data to measure it are available. However, at any given moment, economic agents are in a position to adjust their money

²⁶ The exact figure is given by Allais "The Influence of the Capital-Output Ratio on Real National Income," *Econometrica*, Oct. 1962, 30, p. 714) as 4.87 per cent.

²⁷ Relations (2.39), (2.43), (2.45), (2.48), and (2.50)

balances M from existing towards desired levels M_D either by spending more or buying less.²⁸

Naturally, this adjustment is never perfect, but it can reasonably be suggested that the discrepancy between the actual and the desired value of money holdings is always relatively small. It then follows that it can be assumed at least as a first approximation that

$$(3.1) \quad \left| \frac{M - M_D}{M_D} \right| < \epsilon$$

where ϵ is a small quantity.

It further follows that it is possible to write as a first approximation

$$(3.2) \quad M_D \approx M$$

$$(3.3) \quad \phi_D \approx \phi$$

with

$$(3.4) \quad \phi = \frac{M}{D}.$$

Likewise as a first approximation, it can be assumed that

$$(3.5) \quad \frac{D}{R} \approx \text{a constant}$$

where R is national income at current prices. Thus we can take

$$(3.6) \quad \phi_D = \frac{M}{R}$$

$$(3.7) \quad x \approx \frac{1}{R} \frac{dR}{dt}.$$

During periods of hyperinflation, the index of activity Q does not in general change appreciably and the relation

$$(3.8) \quad \frac{R}{P} \approx \text{a constant}$$

where P is the price index, can be assumed. It follows that for these periods, it is possible to take

$$(3.9) \quad \phi_D = \frac{M}{P}$$

²⁸ This is naturally only an assumption, but as will be seen, it is one which is justified by its consequences.

$$(3.10) \quad x \approx \frac{1}{P} \frac{dP}{dt}.$$

B. *The Available Statistical Data*

Discrete weekly, monthly, quarterly, or annual series are available directly or may be calculated for the values

$$M_n, R_n$$

or

$$M_n, P_n \text{ (hyperinflations)}$$

from which series we can derive the values of

$$(3.11) \quad \bar{x}_n = \frac{1}{p} \ln \frac{R_n}{R_{n-1}} \quad \left(\text{or } \frac{1}{p} \ln \frac{P_n}{P_{n-1}} \right)$$

where p is equal to 0.2308, 1, 3, or 12, according to whether the series considered is weekly, monthly, quarterly, or annual, the time unit being the month. χ_n represents the average rate of growth of total outlay between t_{n-1} and t_n .

Fifteen series have been analyzed for nine countries. The data used were those of M. Friedman and M. Allais for the United States, Great Britain, and France, while P. Cagan's figures were used for the seven hyperinflations considered.²⁹

C. *Fitting of the H.R.L. Formulation*

From (3.2) and (3.6) it is possible to use

$$(3.12) \quad M^* = R\phi_D$$

as an estimate of M . Then, from (2.38)

$$(3.13) \quad M^* = \phi_0 R \psi^*(Z)$$

where $\psi^*(Z)$ represents the theoretical value of ψ , given by (2.51), with Z determined by the differential equation (2.52). Thus³⁰

$$(3.14) \quad M^* = \frac{2\phi_0}{1 + e^Z} R$$

$$(3.15) \quad \frac{dZ}{dt} = x - 0.002(1 + e^Z)Z$$

with

²⁹ For a discussion of the data used and their characteristics, see [8, pp. 45-63] and [9].

³⁰ Relations (2.51), (2.52) and (2.2).

$$(3.16) \quad x(t) = \frac{1}{R} \frac{dR}{dt}.$$

If the R_n are taken as given so that the \bar{x}_n are also given, Z_n can be calculated by integration of (3.12) from the values of \bar{x}_n and the initial value Z_1 of Z . If a value of ϕ_0 is then taken, M^* can be calculated from equation (3.14). For hyperinflations, of course, the index of national income R is replaced by the price index P .

In each case, the values of the two constants Z_1 and ϕ_0 have been fixed by the condition that

$$(3.17) \quad e^2 = \frac{1}{N} \sum_{n=1}^{n=N} [\ln M_n - \ln M_n^*]^2$$

be a minimum, i.e., by the condition that the sum of squares of the deviations of the calculated from the observed values of the logarithm of M is a minimum. This condition is considered as the criterion of the best possible fit. The minimum e^2 of e^2 can be considered as a coefficient which represents the goodness of the fit.

Practically, rather than consider the initial value Z_1 of Z , it is more convenient to consider the coefficient k defined by the relations

$$(3.18) \quad \begin{cases} Z_1 = k(Z_1) \\ \phi_1 = \frac{1+b}{1+be^{\alpha(Z_1)}} \\ \phi_0 = \frac{1+b}{1+be^{\alpha(Z_1)}} \end{cases}$$

where Z_1 is the value of Z at the initial instant t_1 considered, and (Z_1) represents what the value of Z_1 would be if the empirical point corresponding to instant t_1 were exactly on the fitted curve. For illustrative purposes, the coefficient of correlation ρ between $\ln M_n$ and $\ln M_n^*$ has been calculated for each series fitted.

Once the two values of k and ϕ_0 are determined, the calculation of $M^*(t)$ from the values of $R(t)$ is completely independent of the values of $M(t)$. These two coefficients ϕ_0 and k appear as constants of integration.³¹

D. Results Obtained for the Nominal Value of Desired Money Balances

The calculations which have so far been made for the nine countries considered at different times show that the course of events is exactly as if social psychological attitudes towards the relative value of desired money balances ψ were practically invariant over time and between different countries and that this invariance is characterized by the three universal constants.

³¹ For details on the computations involved in fitting the data, see [8, pp. 96-101].

$$(3.19) \quad \alpha = 1 \quad b = 1 \quad \chi_0 = 0.004$$

Three countries were studied for the whole of the period 1900–1960: France, the United Kingdom, and the United States.³² Six more countries were studied during periods in which their economies were dominated by hyperinflationary conditions: Germany, Austria, Greece, Hungary, Poland, and Soviet Russia. Table 2 gives the principal results corresponding to the fitting of the same H.R.L. law ($\alpha=1$, $b=1$, $\chi_0=0.004$) to the relevant series.

The parameter p corresponds to the number of months between two successive observations, and n the number of observations. ρ is the coefficient of correlation between the observed and calculated values of $\ln M_n$ and $\ln M^*$, so that $1-\rho^2$ represents the unexplained part of the variance of $\ln M_n$.

It can be seen that the coefficients ϵ^2 in general have very low values. If the coefficients of correlation are examined, it will further be observed that out of fifteen coefficients eleven exceed 0.99; eight are equal to or greater than 0.995, while there are two whose value exceeds 0.999.^{33,34,35}

By way of illustration, the values of M_n and M_n^* are plotted against time in Charts 2, 3, 4, 5, 6 for France (1919–1938), United States (1918–1941), Germany (December 1919–October 1923), Hungary (July 1945–July 1946), U.S.S.R. (January 1922–February 1924). The German fitting is particularly excellent. The values of (ψ_n, ψ_n^*) are plotted in Chart 7 as a function of Z_n for France (1947–1962), the United States (1918–1941), Germany (Dec. 1919–Oct. 1923), corresponding in all to 87 pairs of values of M and R . The coefficients of correlation between the 87 pairs of values of ψ_n and ψ_n^* and $\ln \psi_n$ and $\ln \psi_n^*$ are respectively 0.9983 and 0.9959).³⁶ Chart 8 shows the values of ψ_n and ψ_n^* as a func-

³² Excluding wartime periods. During such periods, the assumption that is translated by relation (3.1) cannot be considered as valid.

³³ These last two results are practically equal to those obtained in simulation runs on artificial series whose structure corresponded exactly to the H.R.L. law. For example, for the 20-term artificial series $n \cdot IA$, the coefficient of correlation between ψ and ψ^* was 0.99976, whereas for the German figures (excluding deposits) over the period March 1920–October 1923, a total of 43 terms, the coefficient of correlation between $(\ln M$ and $\ln M^*)$ was 0.99987.

³⁴ Naturally, if shorter series only are fitted, it is generally possible to obtain better fits. Lack of space precludes their presentation here. See [6].

³⁵ It is interesting to note that if the differential equation (2.43) in Z is integrated using the observed values $\psi(Z) = \phi(Z)/\phi_0$ instead of the theoretical values $\psi^*(Z)$ as calculated by (2.51), the results are less good. For example, for Germany (15th Dec. 1919–16th Oct. 1923, including deposits), the lowest value of ϵ^2 corresponding to the integration using the $\psi(Z)$ is 0.019, whereas it is 0.0032 using the $\psi^*(Z)$.

³⁶ The respective regression equations are

$$\begin{aligned} \psi &= 0.9872 \psi^* + 0.0037 \\ \ln \psi &= 0.9991 \ln \psi^* - 0.0030 \end{aligned}$$

tion of Z_n for the fifteen numerical series in Table 2, in total 389 pairs of values of M and R . The coefficients of correlation between the 389 pairs of values of ψ_n and ψ_n^* and $\ln \psi_n$ and $\ln \psi_n^*$ are respectively 0.9984 and 0.9930.³⁷

³⁷ The respective regression equations are

$$\begin{aligned}\psi &= 0.9965 \psi^* - 0.0016 \\ \ln \psi &= 1.0087 \ln \psi^* - 0.0076\end{aligned}$$

E. *The Significance of the Results*

As has been seen, the fitting of the time series M , R for a given country over a given period using the same formulation with the same constants

$$\alpha = 1 \quad b = 1 \quad x_0 = 0.004$$

depends only on the two constants of integration ϕ_0 and Z_1 , or ϕ_0 and k . Overall, the agreement between the values forecast by the theory and the observed data is surprising. It goes far beyond what could reasonably have been hoped for on a priori grounds. The values of ϵ^2 and $1-\rho^2$ are so low that the degree of explanation can be considered as complete. The fact that the *same curve* could be fitted to *all* empirical data is the more remarkable when it is considered that, for example, the highest and lowest values of the index of national income in the United States between 1918 and 1941 were 1.08 and 2.84, whereas between December 1919 and October 1923, the index of prices in Germany varied from 15 to 1.09×10^9 , while for Hungary, between July 1945 and July 1946, a base value of 105 rose to the astronomical figure of 4×10^{29} .³⁸

Once the integration constants k and ϕ_0 have been chosen, the numerical integration of equation (3.15)

$$(3.20) \quad \frac{dZ}{dt} = x - 0.002(1 + e^Z)Z$$

and the calculation of the M_n^* using relation (3.13)

$$(3.21) \quad M^* = \frac{2\phi_0}{1 + e^Z} R$$

with

$$(3.22) \quad x = \frac{1}{R} \frac{dR}{dt} \quad \left(\text{or} \quad \frac{1}{P} \frac{dP}{dt} \quad \text{for the hyperinflations} \right)$$

depends only on the value of R or P . The value of M does not enter into the calculation in any way. Thus, once the integration constants k and ϕ_0 are established, the calculated values, M_n^* , are wholly independent of the observed values of M .^{39,40}

³⁸ See Charts 2, 3, and 4.

³⁹ But, of course, the criterion that the arbitrary coefficients ϕ_0 and k which represent the constants of integration should be so chosen as to minimize ϵ^2 means that both of these parameters depend on the observed values of M_n .

⁴⁰ Moreover, it can easily be shown that the influence of the initial value Z_1 of Z , i.e., of the coefficient k , fades progressively, and that it has an asymptotic value of 0. It follows correspondingly that the values of ψ_n^* for the end-period observations are practically independent of the selected value of k , whose influence is restricted to the beginning-of-period values of ψ_n^* .

The results that have been obtained are so extraordinarily close that they seem too good to be true; they lead one to wonder whether they are not necessarily so close, i.e., whether there may not be some implicit circularity. The answer is simple. As the relationships are defined, each curve fitted to the data depends only on two arbitrary parameters. This means that on the graph of M and M^* it is possible to arrange for the terminal points of the curves that represent M and M^* to coincide. But when this condition has been fixed there are no longer any degrees of freedom, and there is no a priori reason for the M and M^* curves to remain near to each other, or indeed to be practically identical to each other, as they are for Germany (Chart 3) over the whole range of variation between the two extreme points. The correspondence that is observed is thus a reflection of the nature of things, and it must be concluded that the observed dependence is indeed a real one.⁴¹

It should further be stressed that the parameters α , m , and χ_0 have exactly the same values for each set of data fitted, and that better results could still be obtained for each country if, as seems reasonable, each parameter were allowed a certain range

$$(\alpha_1, \alpha_2), \quad (b_1, b_2), \quad (\chi_{0,1}, \chi_{0,2})$$

of variation about the central values $\alpha=1$, $b=1$, $\chi_0=0.004$. Such a possibility can improve the results, but without greatly affecting their conceptual and economic significance. The values $\alpha=1$, $b=1$, $\chi_0=0.004$ are in any event only orders of magnitude which it seems perfectly reasonable to assume. Thus, in the same way as the pure rate of interest may vary over a certain range, it is reasonable to envisage that the rate χ_0 may fluctuate about a certain average value.⁴²

From the discussion above, the value $\chi_0=0.004$ can be validly retained only in cases in which the equilibrium level of the pure rate of interest is in the region of 0.4 per cent per month, i.e., 5 per cent per annum. If this condition is not met, other values of χ_0 should be used. It should be added that the better the statistical quality of the time series used, the better the fit obtained. In fact, the curve fittings that are relatively speaking the least satisfactory concern time series whose statistical quality can be seriously questioned.⁴³ In any event, the slight

⁴¹ On the testing of the results see [8, p. 143, note 120].

⁴² As a matter of fact, if it is assumed that the parameters α , b , and χ_0 can take any value whatsoever for each series studied, better results still can be obtained, with reductions of the values of e^2 and $1-R^2$ of the order of 2 to 1 or more in certain cases. When considering relatively long periods in which structural changes have occurred, the results can be further improved by introducing an exponential trend of the form

$$\phi = \phi_0 e^{\rho t} \psi(Z).$$

These results will be described in a separate paper.

⁴³ It may also be remarked that if the three postulates VI, VII and VIII concerning the con-

rences between M and M^* are merely the reflection of the gaps

$$) \quad M - M_D = M - M^*$$

between actual and desired cash balances. The theory here presented has no implication that the gap is zero; merely that it is small. In the author has shown elsewhere that the difference $M - M_D$ (which may be termed the inflationary or deflationary gap, as the case may be) plays a decisive role in monetary developments, and that at least as an approximation we can write the relation (1.10).⁴⁴ The determination of the inflationary gap which is rendered possible by the present theory can clearly be of great importance for the implementation of monetary policy.

Finally, to the extent that the formulation obtained can be considered as valid, it becomes possible to make meaningful comparisons between situations that are a priori incomparable, since the intensity of a hyperinflationary situation can be measured by the rate Z , which has intrinsic significance. Thus the Polish hyperinflation of November 1923 may be compared with the German hyperinflation of July 1923, the two corresponding values of Z being 4.60 and 4.56 respectively.

IV. *The Economic Significance of the Formulation*

The H.R.L. Formulation

The aim of the formulation proposed here is to give operational content to the quantity theory of money, by showing that the velocity of circulation of money at any given moment can be very closely described as an invariant functional of all the earlier rates of growth x of total supply defined by (2.7). It shows that this function can itself be expressed very simply as a function of a rate Z , designated as the psychological rate of expansion, and defined by the differential equation (3.1). The evidence provided by the series studied to date suggests that the interdependence of V (or ϕ) and Z appears to be the same at all times and in all places. Thus the formulation proposed in this paper constitutes a key to the placing of all the known facts within a single framework.

Desired money balances M_D are defined as the product of relative

in §18 were not retained, but the assumption of a common law were maintained nevertheless, the common values of the parameters α , b , and X_0 would no longer be determinate and then be chosen in such a way as to render the overall fitting of the curves as close as possible to the data. In this case, the H.R.L. law ($\alpha=1$, $b=1$, $X_0=0.004$) would no longer be the best common law conceivable, although it would doubtless represent a good approximation. In other words, from this point of view, excellent as the results appear to be, they could probably be further improved. The degree of improvement, however, would of course be less than the possible improvement, under the assumption that α , b , and X_0 are necessarily identical for all the series considered (note 42 above).

Allais, 1954, A non-linear model of cyclical fluctuations [3, §8, relation (7), p. 186].

desired cash balances ϕ by total outlay. Relative desired money balances are moreover nothing other than the coefficient K of the Cambridge school. The proposed formulation is hereditary in the sense that it establishes a functional dependence between the demand for money as recorded at any given moment and the previously observed values of the rate of growth of total outlay. It is relativistic in the sense that this dependence can be given a simple formulation in terms of a psychological time-scale. Finally, it is logistic, in the sense that it leads to a logistic curve when the expression of relative desired money balances is considered as a function of the psychological conjunctural index.

The eight postulates on which the H.R.L. formulation is based are not indissolubly linked to each other. While the hereditary and relativistic postulates do seem to form a unit, the logistic postulate, despite its appeal, need not necessarily be retained. In the same way, Postulate VIII on psychological temporal symmetry is completely independent of the remaining two postulates VI and VII on the constants α and b .

B. *The Economic Interpretation of the Results*

The results obtained can be interpreted in either of two ways, according to whether the expression for relative desired money balances or the interrelationship of the price level and the quantity of money is being considered. These two interpretations, however, correspond to one, and one only, underlying reality.

Relative desired money balances which differ little from the reciprocal of the velocity of circulation may be taken first. Their level is expressed as a determinate function

$$(4.1) \quad \phi_D = \phi_0 \psi(Z)$$

of an index of psychological expansion, which in its turn is a determinate function of the historical development of total expenditure.⁴⁵

If instead of considering relative desired money balances, attention is focussed on V , the velocity of circulation, then

$$(4.2) \quad V \approx \frac{1}{\phi_0 \psi(Z)}^{46}$$

Since

$$(4.3) \quad \begin{aligned} \phi_D &= M_D / D \\ &= M_D / PQ \end{aligned}$$

so that

⁴⁵ Or, in hyperinflations, of prices.

⁴⁶ From (2.4), (3.1), and (3.4).

$$(4.4) \quad M_D = PQ\phi_D$$

whence it follows that, at any given moment, desired money balances are proportional to the product of the price level and the level of economic activity.

Turning to the link between prices and the quantity of money, expressed by the relationship

$$(4.5) \quad P \approx \frac{1}{\phi_0\psi(Z)} \frac{M}{Q}^{47}$$

it can be seen that, at any given time, there is a proportional relationship between the price level and the quantity of money. But the coefficient of proportionality is not constant; its value at each moment depends on the past historical development of total outlay. Thus, the quantity theory of money appears to be fundamentally correct, provided that it is redefined on the basis of the hereditary and relativistic formulation which has been presented above. The velocity of circulation which is inversely proportional to relative desired money balances is not a constant, but appears as an invariant function of past developments.

The link of proportionality at any given time between the quantity of money and the product of the price level and the level of activity (relation 4.5) is a relationship of interdependence, and from the dynamic standpoint of causality can obviously be interpreted in either of two ways. It may mean that the price level is proportional to the ratio of the quantity of money to the level of activity; or it may mean that the quantity of money is proportional to the product of the price level and the level of economic activity. The examination of this double interpretation is beyond the scope of this study. In general, both viewpoints are valid, for in changing economic situations, effects influence causes, and different weights must be given to the one or the other according to circumstances. In some cases, it may be the first interpretation which applies,⁴⁸ whereas at other times the second may provide the explanation of what constitutes the motive force.⁴⁹

The theory proposed here makes possible a new, operational reformulation of the quantity theory of money, and enables a synthesis to be made of points of view which hitherto have been considered as completely opposed. The standpoint of the quantity theorist is validated in as much as there is a proportional relation between prices and the quantity of money. But so is the anti-quantity theory view since the coefficient of proportionality is not constant. Clearly, considered in itself the formulation of the demand for money does not and cannot

⁴⁷ Which follows from (2.4), (2.13), (2.31), (3.3), and (3.4).

⁴⁸ This is so, for example, of inflations reflecting the growth of the means payment (inflation in the 16th century, hyperinflation, etc.).

⁴⁹ E.g., wage inflation (as in France in 1936 and 1945, etc.).

constitute a theory of monetary dynamics. It is but one element of a much greater whole;⁵⁰ but it is obviously an element of considerable importance. The only aim of the H.R.L. formulation is to specify how, at any given moment, the demand for money and the velocity of circulation are determined.

C. *The H.R.L. Formulation and Previous Researches*

It may be of help to show very briefly the relation of the present H.R.L. formulation to earlier formulations. Fundamentally, "desired money balances" M_D in this paper is none other than Walras' "desired money balances," but the concept of relative desired money balances ϕ_D corresponds to the coefficient K in the Cambridge formulation, and in fact is little different from the reciprocal, $1/V$, of the velocity of circulation, V , in Newcomb and Fisher's formulation.⁵¹ Cagan's 1954 formulation has been compared with Allais' 1954 formulation in the introduction of this paper.

The present Allais formulation (1963) differs from the 1954 Allais formulation in that the two equations (1.1b) and (1.2a) are replaced by the two equations

$$(4.6) \quad \phi_D = \phi_0 \frac{1+b}{1+be^{\alpha Z}}$$

$$(4.7) \quad \frac{dZ}{dt} = x - x_0 \frac{1+be^{\alpha Z}}{1+b} Z$$

By contrast with all earlier formulations, the theory underlying both Allais' formulations (1954 and 1963) is based on the existence of a nonzero difference $M - M_D$ between the supply of and the demand for money. This difference determines changes in total outlay D by the equation (1.10). The fact that this difference remains small enables empirical study of relative desired money balances to be founded on the assumption that for practical purposes the two quantities are equivalent (condition 3.2).

The essential differences between the H.R.L. formulation of 1963 and Allais' and Cagan's 1954 formulations are: (a) the coefficient \bar{x} of forgetfulness is no longer a constant, but a function of the index $\psi(Z)$ which satisfies the condition (2.41); (b) the function ψ , instead of being exponential (Cagan) or linear (Allais 1954) in u , is a logistic function of Z . Further, in the context of analysis of the current situation, there is the essential point that Allais' formulations of 1954 and 1963 differ from Cagan's formulation, in that Allais defines x by (1.3b), whereas in Cagan's formulation it is defined by (1.3a). In fact, defining x by (a)

⁵⁰ In my papers of 1953 [2], 1954 [3], and 1955 [5] I have tried to trace the outlines of such a theory; see in particular relation (1.10) above.

⁵¹ See Allais [8, pp. 33-34 and 153-54].

results in a less satisfactory fit of the data than when (b) is used. This is because definition (b) takes account of both changes in the price level and changes in the level of economic activity, and correspondingly provides a better image of the development of the economic situation.⁵²

The superiority of the H.R.L. formulation over Cagan's formulation can be assessed by comparing the periods covered, and the values of N and $1-\rho^2$, as between Tables 1 and 2. The main advances represented by the H.R.L. ($\alpha=1$, $b=1$, $X_0=0.004$) formulation by comparison with Cagan formulation are a better fitting of short series,⁵³ the possibility of fitting long series, the applicability of the same formulation to different situations. The H.R.L. common law generally offers a better description of the facts than the earlier Cagan or Allais formulations, though the characteristic parameters in the latter varied from one series to the next⁵⁴ and though the number of arbitrary parameters is two instead of three.

According to Friedman's and Cagan's view, the coefficient u (or E)⁵⁵ appears as a "coefficient of expectation" and it is quite natural to assume that the expected rate of change du/dt of the rate of expectation u is determined in each period of time in proportion to the difference between the actual rate of change x of total outlay D and the rate of change u that had been expected (differential equation 1.2a). According to Allais' view in 1954, u is related to the past and not to the future. This rate reflects the memory of the past retained by economic agents, and the farther back in the past that events are recalled, the more it fades. When the coefficient of forgetfulness \bar{x} is constant the two formulations (1.2) are mathematically the same, but their philosophical starting points are different. Since Cagan's and Allais' 1954 views are merely two different interpretations of the same mathematical formulation there is no point in suggesting that either is superior.

The new H.R.L. formulation which is proposed in this paper differs from Allais' earlier formulation and the Cagan and Friedman formulations in that it takes the psychological time scale into consideration. Here, from the differential equation (2.27) it is no longer possible to interpret the rate of expansion z as being proportional to the difference $x-z$. On the contrary, the new formulation appears to be a quite natural generalization of Allais' earlier conception.⁵⁶ To the extent that formulation gives better results, Allais' view appears to correspond better to the real nature of the facts.

⁵² For further details on the comparison of the present formulation and those which have been put forward in the past, see [8, Table VI, p. 154].

⁵³ Allais [8, Tables IX and X, pp. 178-79].

⁵⁴ For further details see [8, Appendix I].

⁵⁵ See Introduction and footnote 2.

⁵⁶ Since from postulate of II.c., relation (1.2) holds when referred to a psychological time scale II.c., relation (2.10).

D. *The Proposed Formulation*

The results show that human societies placed in very different circumstances, ranging from normal situations to hyperinflations, in capitalistic or communistic regimes, today or a half-century ago, react according to one and the same law, one which moreover might validly have been deduced from a priori reasoning. This similarity of behavior should be interpreted as corresponding to the invariance of human psychology in space and over time, at least in its collective aspect.

In fact, the proposed formulation can be applied in numerous other fields. The index of psychological expansion, which can easily be calculated at any time, provides a quantitative measure of the economy's appreciation of the conjunctural situation.⁵⁷ It is therefore very probable, if not certain, that the introduction of this index into economic forecasting and analytical calculations would greatly improve both the analysis of past developments and the methods employed for making projections.

The results obtained in this study of monetary phenomena are no more than an illustration of the importance of hereditary and relativistic effects in the behavioral sciences. There is no doubt that these phenomena are merely one particular example of many cases in which the methods and principles would be valid over the whole range of social phenomena to the extent that these phenomena are linked by relationships of a hereditary type, and to the extent that time scales are subject to relativistic effects.⁵⁸

The proposed formulation may at first sight appear to be complex. But it is verified by the available empirical data, at least in the cases studied up to now. So long as fresh data do not invalidate it, it must be considered as corresponding to the nature of things. Whether the hereditary, relativistic, and logistic formulation ($\alpha=1$, $b=1$, $X_0=0.004$) is confirmed or invalidated as a general law by the analysis of further numerical series,⁵⁹ the numerical regularities which have been brought out will stand. As with other theories, so with this one. Its logical formulation may be maintained or modified, but the real relationships between observable quantities which it has brought out will have been established once and for all, and this is certainly what must be considered as the essential contribution of this study.

⁵⁷ In French "Situation conjoncturelle." See footnote 22 above.

⁵⁸ From relations (2.2), (2.26), and (2.29) the function $\psi(Z)$ represents the value of the unit of psychological time for society as a whole as a function of the intrinsic rate of expansion Z .

⁵⁹ The author of this paper would be grateful to receive time series (M_n, R_n) or (M_n, P_n) relating to any country and covering any period for purposes of analysis. Monthly values are preferable, if they can be supplied.

THE PROPENSITY TO CONSUME PERMANENT INCOME

By THOMAS MAYER*

This paper compares the average propensity to consume at different levels of permanent income, thus testing a hypothesis of a modified permanent income theory. The modification is the treatment of consumer durable purchases as consumption—a modification defended below. The test deals only with the hypothesis that the average propensity to consume is independent of the level of permanent income; it says nothing about the other main component of the permanent income theory, the lag hypothesis. I will use the term “permanent income theory” in the strict sense, i.e., as *inter alia* an assertion that the marginal propensity to consume is independent of the level of permanent income. In addition to testing this strict theory, I am also testing the looser version of the theory, namely, that the marginal propensity to consume is greater for permanent than for measured income, though even for permanent income, the marginal propensity to consume is less than the average propensity. There is considerable evidence both for and against the strict permanent income theory, which suggests that the truth may lie somewhere in-between, i.e., that the looser version of the theory is correct. The test presented in this paper goes beyond such a vague supposition and actually measures the *extent* to which the modified permanent income theory is correct.

The main problem in testing the permanent income theory is to obtain an empirically measurable proxy for permanent income. I have used the mean income of broadly defined occupational groups. There are two ways in which the mean income of an occupational group may fail to be an adequate measure of the mean permanent incomes of its members. First, households may change their occupations and, second, the mean income of occupations may fluctuate over time. I have guard-

Strassmann, as well as to members of the Continuing Seminar in Money and Banking of the University of California, Davis, and Professor Brunner's seminar at UCLA where earlier versions of this paper were read. He is indebted for financial support to the University of California, Davis, for a faculty research grant, to the Institute of Industrial Relations of the University of California, and to the Davis and Berkeley computer centers of the University of California. Finally, he is indebted for providing unpublished data to the Institute of Economics and Statistics of Oxford University and the Survey Research Center of the University of Michigan.

ed against the first of these dangers by using broad occupational classes such as manual workers vs. white collar workers. Movement between such broad classes is quite infrequent,¹ particularly in pre-World War II Europe, the source of some of the data. I have guarded against the second danger by using thirty-four budget studies spread over the period 1912-1961 covering a dozen countries. Given such a large sample, differences in the receipt of transitory income among occupations should cancel out, so that differences in the mean income of occupations reflects *on the average* (though not necessarily in any single case) differences in permanent income. Using the income of occupations as proxies for permanent income is not a new idea; in fact, this has been done by Modigliani and Ando [23] on one side of the debate and by Friend and Kravis [9] on the other.² However, both of these tests relied on a single budget study, the 1950 Bureau of Labor Statistics Survey; but for any single year there is no justification for assuming that transitory elements average out within each occupation. It is quite possible that certain occupations had positive, and others negative, transitory income in that year. Moreover, the validity of the 1950 data is doubtful [10] [23]. In addition, neither the Modigliani-Ando study nor the Friend-Kravis study tested the looser version of the theory.³

I. Method

One advantage of an occupational test is that it does not require any elaborate and essentially untested methods—a simple comparison of average propensities to consume of different occupations is all that is required to see if the strict theory is valid. And an only slightly more complex procedure allows one to determine the extent to which the looser version is valid. This procedure consists of computing the marginal propensity to consume twice, once from households grouped by occupation, and once from the *same* households grouped by income class (i.e., by measured income). If the permanent income theory is entirely correct, then the marginal propensity to consume, when computed from the occupational grouping, should on the average equal the average propensity to consume. On the other hand, assume that the

¹A large-scale study [19, p. 161] of occupational mobility undertaken in Oakland, California, in 1949 found considerable stability of broad occupational affiliation in spite of the preceding war and depression years. Similarly, a Swedish study for the periods 1930-36 and 1940-45 shows relatively little mobility [2].

²Friedman, too, uses an occupational test [8, pp. 69-79], but one that differs from the test used here. As is shown below, this test is based on inappropriate data. Another occupational test which has some similarity with the one present here was undertaken by Houthakker [12] and led to a debate with Eisner and Friedman [5, 7, 13].

³Both the tests reject the permanent income theory, though some of the other tests used by Modigliani and Ando do not.

permanent income theory is completely wrong, and that it makes no difference whether one uses permanent income or measured income in estimating the consumption function. If so, the marginal propensity to consume should, on the average, be the same when households are classified by measured and by permanent income.

These two alternatives, as well as the intermediate cases, can be exhibited by the statistic $c_o - a/c_v - a$ where c_o is the marginal propensity to consume computed from an occupational grouping of the households, c_v is the marginal propensity measured from an income class grouping of the households, and a is the average propensity to consume. The denominator measures the gap between the marginal and average propensities to consume when this gap is calculated conventionally, i.e., when measured income is used. The numerator, on the other hand, measures the gap between the marginal and average propensities which remains even if one uses permanent income instead of measured income. The expression, therefore, shows the remaining gap as a proportion of the conventionally computed one. Thus, it has the convenient property that if the modified permanent income theory is completely right, the numerator, and hence, the whole expression, is zero, while if the theory is completely wrong, its value is unity. And similarly, intermediate cases give a value between zero and unity. For example, if the average propensity to consume is 0.8 and the marginal propensity to consume is 0.7 for permanent income and 0.6 for measured income, the coefficient has a value of 0.5.

I have called this expression the prediction coefficient because it measures the extent to which the conventional theories (the name I will use hereafter for the absolute and relative income theories) predict correctly. One can look upon the permanent income theory as a naive theory which asserts that the percentage of income consumed is independent of the level of permanent income, while the conventional theories represent attempts to go beyond such a naive model, and to predict the percentage of income consumed from a knowledge of the level of income. Traditionally, computations of the average and marginal propensities to consume based on *measured* incomes have suggested that the conventional theories are superior to a naive model; but they involve a possible bias, which according to the permanent income theory accounts fully for their apparent superiority. The prediction coefficient is a device which measures the extent to which the superiority of the prediction survives the elimination of this bias.

In computing the marginal propensity to consume, I have used quite simple consumption functions, primarily because the data were insufficient to fit more complex ones. Most budget studies do not give information about the many variables usually included in elaborate

multivariate functions. Moreover, even when such information is available (as in the *Survey of Consumer Finances*) there are too few occupational groups (and hence, too few degrees of freedom) to fit elaborate functions. Fortunately, the use of a simple consumption function does not do violence to the theories being tested.⁴

However, I have, when feasible, included household size as an additional independent variable. The number of persons per household is clearly one of the important determinants of consumption. Moreover, this variable becomes particularly significant when comparing the marginal propensity to consume of households as computed from an occupational grouping with the same propensity computed from an income class grouping. When households are grouped by measured income, there is a positive relation between income level and family size. But if households are grouped by occupation, there exists, in the data used here, no such positive correlation. Hence, a bias may be created if family size is ignored.

I computed the marginal propensity to consume in two different ways. In those cases where I had three or more occupations I used regression analysis. But in those cases where I had only two occupations I computed the marginal propensity to consume permanent income by subtracting the mean consumption of one occupation from that of the other and dividing by the difference in mean income. Correspondingly, in these cases I calculated the marginal propensity to consume measured income by dividing the households in each occupation at the median income of that occupation and then dividing the difference in consumption of households above the below and median by the difference in mean income.⁵ For reasons discussed below and in a duplicated appendix [21] available upon request, I have treated the individual budget studies as separate units.

⁴Friedman himself, though not Modigliani, uses a simple function, explicitly rejecting the more ponderous consumption functions fitted by others. And the same holds true on the other side of the debate. In the relative income theory Duesenberry uses as independent variables only income and mean income of the community (or else previous peak income), and since the last two variables are not relevant for an occupational test, a simple consumption function is a fair test. Similarly, the absolute income theory, while it may use several independent variables, is basically an assertion that the higher the level of income, the lower the percentage consumed even if other variables are left out of consideration.

⁵A number of budget studies did not cover the two occupations in proportion to their frequency in the universe. In these cases I averaged the marginal propensities to consume of the two occupations by giving the marginal propensity to consume of manual workers twice the weight of the marginal propensity to consume of clerical workers. In the countries covered by these budget studies nonagricultural manual workers were somewhat more than twice as numerous as clerical workers [35], but since their average income was lower, a two to one ratio gives an adequate approximation to the relative importance of these two groups as income receivers.

II. *Measurement of Permanent Income and Consumption*

The use of mean measured income of an occupation as a proxy for the permanent income of its members requires several safeguards. One, already mentioned, is to use many budget studies so that differences in transitory income cancel out. Another safeguard is to decide which is the higher-paid and which is the lower-paid occupation, not on the basis of mean measured income in the particular budget study, but on an *a priori* basis, i.e., to make this decision on the basis of one's knowledge about the relative income of occupations before even looking at measured incomes in the particular budget study.⁶ To facilitate this decision I have used broad occupational groupings. While it may be difficult to decide *a priori* whether, say, metal workers have a higher income than wood workers, it is easy to decide that skilled workers have a higher income than unskilled ones. Still another safeguard is to exclude certain occupational classifications such as "unemployed" or "retired," which are clearly dominated by transient households.

Turning to consumption, the main definitional problem is the treatment of consumer durables. I have treated the purchase of consumer durables as consumption, a choice largely dictated by the data, and hence I am testing a *modified* version of the permanent income theory. This modification can be defended on two grounds. First, most of the data cited by Friedman and Modigliani, as well as others, in support of the permanent income theory include the purchase of consumer durables in consumption. If such data are allowed to confirm the theory, they must be allowed to reject it too. Second, in a more positive vein, for the great preponderance of macro-economic problems, the relevant definition of consumption is one which *includes* consumer durable purchases. Thus, in Friedman's discussion of the policy implications of the permanent income theory, the problems he lists are better served by a definition of consumption which includes durable purchases [8 pp. 235-38]. Hence, whether or not my data constitute a fair test of the permanent income theory, they do deal with an important policy parameter, the marginal propensity to consume as conventionally defined.

Another problem is the treatment of insurance. When insurance is stated separately, I have included life insurance (and burial insurance) premiums in saving for reasons discussed in [21]. In some studies all insurance premiums were given as a single item. In these

⁶ In only a few cases did I look at the relative incomes of the occupations before making the decision, and even then I did not attach much importance to the ranking in the particular study. Only those budget studies in which the actual income ranking did correspond to *a priori* expectations were used.

cases I have computed the coefficients twice, once including insurance premiums in saving and once excluding them. Some other measurement problems are discussed in [21].

III. *The Sample*

I have attempted to include with exceptions described in [21] all budget studies since 1900 that provide useable data.⁷ Since only a relatively small proportion of the numerous budget studies undertaken in this period give data on occupations, this turned out to be a feasible task. The use of early budget studies may need justification since we are primarily concerned with the present. Such a justification is given in [21].

I have not used all occupations given within each study, but limited the analysis to those occupations for which one would expect a clear-cut income difference. Thus, the most common distinction used is that between manual workers, on the one hand, and white collar employees or officials on the other. One important exclusion is self-employed households. In addition to the fact that the data for such households are particularly unreliable, they must be excluded because both the permanent income theory and the more conventional theories assert—though for different reasons—that entrepreneurial households save more than nonentrepreneurial households. Hence, a comparison of the propensities to consume of entrepreneurial and other households can neither support nor reject the permanent income theory. Finally, I have, in all but one case, excluded farm worker households and armed forces households because of the problems created by their receipt of non-money income.

IV. *The Results*

Table 1 shows the budget studies used, the coefficient of ranked correlation between the mean income of the occupation and the average propensity to consume, and for those cases where it could be com-

⁷ The main exclusions are budget studies (1) for underdeveloped countries and iron curtain countries, (2) for the immediate post-World War II years, (3) covering less than a full year with one exception, (4) showing a rising marginal propensity to consume measured income, (5) based on an inadequate number of cases or available only in inadequate secondary sources. In addition, to keep the sample balanced, I did not—with one exception discussed in [21]—use budget studies for more than three consecutive years for the same country.

One obvious omission is the large scale 1935-36 *Survey of Consumer Purchases* study used by Friedman in his occupational test [8]. The reason for its omission is that it excluded from its tabulation of income and consumption by occupation all households with incomes outside the normal range for their occupation. Since the proportion of transitory income excluded in this way is likely to vary for each occupation, any test of the permanent income theory based on these data is inadequate.

In locating the earlier studies I was aided by a magnificent annotated bibliography [25].

TABLE 1—RANKED CORRELATION COEFFICIENTS AND PREDICTION COEFFICIENTS

Locality	Date of Study ^a	RHO ^b	Prediction Coefficient	Occupations Covered and Number of Households ^c	Method of Computing Prediction Coefficient ^d	Source

U—unskilled manual workers

W—manual workers

WC—working class

^d R denotes multiple regression, using income and household size as independent variables. Household size is measured sometimes by number of persons and sometimes by number of consumption units. M denotes that income classes were split at median and that no adjustment for household size was made.

^e Insurance premiums treated as saving.

^f Insurance premiums treated as consumption.

^g Middle rank officials and teachers only.

^h I regrouped data into two classes: (a) teachers, middle rank government officials and government white collar employees, and officials of private enterprises (44 households); (b) lower ranking white collar employees of private enterprise and manual workers (41 households).

ⁱ Lower ranking white collar employees only.

^j The data understate saving and income, and since this understatement is greater for the lower income group than for the upper income group, there is a bias in favor of the permanent income theory.

^a Number of cases in each group is approximate only.^r Five hundred forty-eight higher officials and employees, 1,132 lower officials and employees, 515 skilled workers, 745 unskilled workers, and 160 agricultural workers.^a Rho is positive if company directors are included in the sample, and negative if they are excluded. The study states that the saving of company directors is understated [17]. Moreover, even if one includes company directors, Rho is -1.0 if receipts from inheritances are included in income.^t Thirty-two company directors, 77 doctors, and 45 dentists.^u Since the relative income position of two of the occupations covered, officials and lower business managers, is unclear, I computed Rho twice—once excluding lower officials and once excluding lower business managers. Rho is -0.9 in the former case and -0.7 in the latter case.^v Twenty-three higher business managers, 34 lower business managers, 70 academically trained employees exclusive of farmers and business managers, 47 higher officials, 185 lower officials, 22 foremen, and 499 workers.^w The marginal propensities to consume of the two occupations are very similar so that it is possible, though perhaps not very likely, that the difference between them is merely the result of differences in household size.^x Occupations used are the same as for 1950. The number of cases in each occupation in the sample is not given. The total sample (including the self-employed and unemployed) amounted to 4,463 households in 1960 and 4,879 households in 1961.

puted, the prediction coefficients. A brief description of the data, of the problems encountered, and the approximations used, is given in [21].

The results shown in Table 1 strongly reject the modified permanent income theory.⁸ The signs of the ranked correlation coefficients show that in only 2 of the 31 unequivocal cases (Zurich 1919 and Czechoslovakia 1925-26) does the higher-paid occupation consume a larger percentage of its income than the lower-paid occupation. And in the former case the result can be explained by the fact that the upper occupations consisted largely of government employees. Since there had been a substantial inflation in previous years [29] the measured real income of this group was presumably below its real permanent income. In 3 additional cases (Netherlands 1951, Great Britain 1955-56, and Norway 1958) there is considerable doubt about the results. But even if one gives these 3 doubtful cases to the permanent income theory, there are only 5 cases out of 34 in which the conventional theories predict incorrectly. The probability of getting that many "successes" merely by "chance" is less than 1 per cent.⁹

It is worthwhile to look not only at all cases jointly, but at their components. First, one may look at prewar and postwar studies separately. There are twelve prewar studies, and in all but two of them the

⁸ The reason why the ranked correlation coefficient is so frequently (minus) one, is that in many studies there were only two usable occupational groups, so that the coefficient has to be (plus, or else, minus) unity.

⁹ The significance test used throughout this paper is a simple binomial test. I have treated each individual study as a unit and not applied significance tests to the difference of the two marginal propensities to consume with each study. Significance tests applied to any single budget study taken in isolation would understate the import of the results. Assume, for example, that in each of, say, six budget studies, the difference between the marginal propensities to consume computed from occupational and from income class groupings is significant only at the 20 per cent level. If the differences are all in the same direction, then the differences for all studies taken together are clearly significant, in spite of the fact that none of the individual studies has significant results at a respectable significance level. Moreover, within a single study, a significance test would have little meaning. One of the disturbances, perhaps the main one, is the existence of positive (or negative) transitory income. There is no reason at all for assuming that *within* any one study transitory income is randomly distributed.

These problems disappear if one takes as the unit of observation, not the individual household, but the whole budget study, treating the propensity to consume of an occupation or income class as though it were the propensity to consume of a single representative household in this group. If one assumes that budget studies occurred in years which were chosen randomly with respect to the distribution of transitory income, one can then apply significance tests to the results. By calling each case where the average propensity to consume of the lower-paid occupation exceeds the propensity of the higher-paid occupation a "success" for the conventional theories, one can see if the resulting number of successes could be due to chance. And similarly, by seeing if the marginal propensity to consume calculated from data grouped by occupations exceeds this propensity as computed from income groupings, one can find the number of successes for a theory which asserts that the marginal propensity to consume is greater for permanent than for measured income. Successes on both tests then support a position intermediate between the permanent income and conventional theories.

conventional theories predict correctly. This is significant at the 3 per cent level. For the postwar period there are 22 studies and, even if one gives the 3 doubtful cases to the permanent income theory, the conventional theories predict correctly in 19 of these 22 cases, a result significant at the 1 per cent level. The fact that the results are significant for each period taken separately is useful because it shows that the outcome is really based on a long period of time and cannot be explained away by the higher-paid occupation having more positive transitory income for a brief span of years.

Another way of separating the data is to select the most reliable ones. There are 19 studies which have a sample of more than 500 households and seem reliable and relevant in every way.¹⁰ These 19 cases do not include the 2 in which the average propensity to consume is clearly less for the lower income group than for the upper income group, though they do include the 3 doubtful cases. But, even if one gives these 3 doubtful cases to the permanent income theory, the conventional theories predict correctly at the 1 per cent significance level.

But the "success" of the conventional theories is a severely qualified one, since it appears that the marginal propensity to consume *permanent* income is greater than the marginal propensity to consume *measured* income. As previously pointed out, in this case the prediction coefficient is less than unity. And this is true for the great majority of the coefficients shown in Table 1. If the doubtful insurance premium in the Amsterdam 1923-24 case is treated as saving, then, of the 20 prediction coefficients, 14 are below unity, 2 are equal to unity, and only 4 are above unity. Treating the doubtful insurance premiums as consumption yields 15 coefficients below unity, 1 equal to unity, and 4 above unity.

To apply a significance test to these outcomes, something must be done about the coefficients of unity—where the coin, so to speak, falls neither heads nor tails, but stands on its edge. If, instead of rounding the prediction coefficients to one place of decimals, one expresses them to two places, one coefficient (Netherlands 1935-36) drops below unity. The other coefficient remains at unity, but fortunately it relates only to the case where the doubtful insurance premium is treated as saving. If one averages the two coefficients, one treating the insurance premium as saving and one treating it as consumption, the resulting coefficient is again below unity.¹¹

Making these adjustments, of the 20 coefficients, 16 are below unity.

¹⁰ I excluded the Japanese study from this set because it covers less than a full year.

¹¹ The coefficient will be less than unity even if one gives most of the weight to the coefficient of unity. It is unity to two places of decimals whereas the other coefficient to two places of decimals is 0.86.

TABLE 2—MEDIAN AND MEANS OF PREDICTION COEFFICIENTS

	Median	Positional ^c Mean Mid 50 Per Cent		Mean		Number of Studies

Source: Table 1.

and the hypothesis that the marginal propensities to consume are the same for permanent and measured income can be rejected at the 1 per cent significance level. Alternatively, if one simply excludes the studies with a prediction coefficient of unity, the results are significant at the 3 per cent level.

Thus the data reject both the modified permanent income theory and the conventional theories and show that the truth lies in between. The prediction coefficients allow one to see where it lies between the two theories. Table 2 shows various averages for the coefficients. The medians and positional means shown in this Table are more meaningful than are the arithmetic means, because the arithmetic means are too heavily influenced by a few extremely large cases. These extreme cases are much less meaningful than the other cases. The prediction coefficient is defined as the percentage of the gap between the average propensity to consume and the marginal propensity to consume measured income which disappears if one uses permanent income in place of measured income. But no such meaning is attached to the prediction coefficient in those cases where the marginal propensity to consume measured income appears to exceed the marginal propensity to consume permanent income, so that the prediction coefficient exceeds unity.¹² In these cases the prediction coefficient is merely a statistical artifact without a useful economic interpretation.

¹² These cases probably result either from errors in the basic data, sampling fluctuations, or, perhaps more likely, from differences in transitory income receipts by various occupations. While these transitory elements should cancel out for all studies jointly, one would expect them to dominate the result in a few cases. Such random factors which raise the prediction

The medians and positional means of Table 2 show that, in predicting the proportion of income consumed, the conventional theories are closer to the truth than is the modified permanent income theory. The medians and positional means suggest that, if one uses permanent income in place of measured income, only about one-third of the difference between the average propensity and marginal propensity to consume disappears.

Table 2 also shows various breakdowns of the overall results. There is no great difference between the results for postwar and prewar studies, and for coefficients estimated by regression and those estimated by comparing only two occupations. This close agreement between the results obtained by these two methods is useful since it suggests that the results cannot be attributed to a bias in the method. Table 2 also shows that the results for selected studies (i.e., the most applicable and reliable ones) are not very different from those for all studies together, thus suggesting that the results are not merely the consequence of errors in the data.

V. *Other Variables*

The negative relation between permanent income and the per cent of income consumed cannot be attributed to chance elements. But this does not necessarily imply that the lower average propensity to consume of the better-paid occupations is due to their higher income. Let us, therefore, look at the variables other than income which are thought to be important for the consumption function and see if they can account for the above results.

In his well-known text, Gardner Ackley [1, Ch. 12] mentions the following variables: the interest rate, consumer credit terms, sales effort, relative prices, deferred demand, the stocks of consumer durables, price and income expectations, income distribution, demographic factors, wealth, liquid assets, the money stock, capital gains, and subjective and cultural factors. To this list the following three variables should be added: frequency of home-ownership, contractual saving commitments, and pension arrangements. Friedman suggests that the main variables determining the average propensity to consume permanent income are: "the rate of interest, the relative dispersion of transitory components of income and of consumption, the ratio of wealth to

coefficient would tend *not* to be fully offset by random factors in the other direction, since outside the zero to unity range the prediction coefficients are not symmetrical. The prediction coefficient will be negative only if the marginal propensity to consume as calculated from occupational income is negative. To be symmetrical, it should be greater than unity only if the marginal propensity to consume *measured* income is negative—but as pointed out above, I have discarded all such cases. Instead, the prediction coefficient exceeds unity if the marginal propensity to consume is greater for measured than for permanent income.

income, and the age and composition of consumer units" [8, p. 232]. In [21] I have examined each of these variables to see if they could account for the above results. Here I will just summarize the results.

The first nine of these variables can be dismissed quickly since they are either not relevant for the cross-section test used here, or else because they would tend, if anything, to increase the average propensity to consume of the higher occupations relative to the average propensity to consume of the lower occupations.¹³ Hence, although some of these factors may perhaps be invoked to explain why the data reject the conventional theories (or why the prediction coefficients have a downward bias), they cannot be used to explain why the data reject the modified permanent income theory.

One demographic variable, household size, has been taken into account in some of the studies. Another one, age, shows little variation among occupations, at least in the United States and Great Britain [18, p. 81] [21, Tables 3 and 4]. Unfortunately, very little information on wealth holdings is available. But some data for Denmark, Britain, and Sweden [32, pp. 24, 63] [45, pp. 71, 179] [21, Table 4] show that the ratio of net worth to income is positively correlated with the mean income of occupations.¹⁴

Incidentally, it is worth noting that the fact that the higher occupations have a greater ratio of wealth to income than the lower occupations is consistent with the hypothesis that they save a larger proportion of their income. And while this fact is not *necessarily* inconsistent with the modified permanent income theory, it can be made consistent with it only by some rather tenuous reasoning.¹⁵

¹³ For simplicity I will use the terms "higher" and "lower" occupations instead of "higher-paid" and "lower-paid". The three variables which may increase the propensity to consume of the upper occupations relative to that of the lower occupations are: the rate of interest paid on borrowing, consumer credit terms, and sales effort. (This makes the conventional assumption that the interest elasticity of saving is positive.)

¹⁴ Unfortunately, the direction of the wealth effect on consumption is not quite certain. The predominant view is that the higher the level of wealth, the lower the saving-income ratio, because the higher the stock of wealth, the lower is the marginal rate of substitution of current consumption for wealth, i.e., for future consumption [1, pp. 269-73] and [24]. But there is a minority view which asserts that an increase in wealth *may* stimulate saving by raising the household's level of aspirations. (See G. Katona [14, pp. 131-37] and L. Klein [15, p. 99].) And there is one fact which appears to support this view: households covered by private pension funds save (apart from the pension system) a higher proportion of their income than households without pensions [4]. If the predominant view is correct, then the fact that I have omitted the wealth variable creates a bias in favor of the modified permanent income theory; while if the other view is correct, there is a bias against the theory.

If the correlation between wealth and mean occupational income is the same as the correlation between wealth and measured income, then the prediction coefficient is unaffected by the omission of wealth, but in other cases, the prediction coefficient may be biased.

¹⁵ The only explanation that seems consistent with the permanent income theory is that there is a positive correlation between windfall receipts by one generation and high occupa-

The next variable, liquid asset holdings, is, at least in the postwar United States and Great Britain, positively correlated with occupational income [20, pp. 54 and 81] [21, Table 4]. Hence if this variable has an effect on the propensity to consume (a proposition frequently denied it) it biases the results in favor of the modified permanent income theory.¹⁶

Next there is homeownership. Unfortunately, the data on the relative frequency of homeownership show an unclear picture. For the postwar period there is no pronounced relationship between occupational status and the frequency of homeownership in the United States in one set of data, but there is such a positive relationship in another set of data [21, Tables 3 and 7]. In Great Britain and Switzerland these two variables are positively correlated, but in Sweden the correlation is negative [20, p. 99] [51, Vol I, p. 269, Vol. II, p. 635] [47, p. 193].

But, in any case, a positive relationship between occupational income and homeownership cannot be invoked to discount the positive correlation between occupational income and the saving ratio. If high income households are more prone to be homeowners than low income households, and if homeownership raises the saving-income ratio, the resulting correlation of income and the saving ratio is not spurious, but measures the *indirect* effect of income differences on the saving ratio.

Turning to the relative dispersion of transitory income and consumption, a greater dispersion leads to greater saving since a household may try to guard against risk by accumulating wealth. The relative dispersion of income is probably greater for the lower occupations than for the higher ones, since unemployment is greater for these occupations, so that this factor, too, produces a bias in favor of the modified permanent income theory.¹⁷

The next variable is capital gains. Fortunately, the fact that I am

tional status of the next generation, so that households with high occupational status tend to have relatively large inheritances. Such a situation is not completely implausible; it could result, for example, from men with high occupational status marrying women whose parents had large positive windfall income, or from parents with large positive windfall incomes providing their children with a better education. But while these explanations are not *completely* implausible, they seem to be rather forced. Hence, the wealth figures provide an additional reason for abandoning the hypothesis that the average propensity to consume is independent of permanent income.

¹⁶ Almost no information is available on the next variable, money holdings, but if we assume that a dollar of money holdings has a roughly similar effect on consumption to a dollar of nonmoney liquid assets, then the problem is less severe because demand deposits are included in liquid assets.

¹⁷ For data on unemployment rates of various occupations in the postwar United States, see [11, p. 62]. These data show substantially greater unemployment rates for manual workers than for white collar employees. The relative dispersion of transitory consumption can be ignored—there is no reason to assume that it varies among occupations.

excluding the self-employed, who presumably account for a large proportion of capital gains, alleviates this problem.¹⁸

The type of pension system is a variable that is frequently omitted from the consumption function; yet it could be important when comparing the propensities to consume of different occupations since they may have different pension arrangements. There are two aspects to this problem. First, since budget studies generally do not count the employers' or government's pension contribution as saving, total saving is understated. Second, it is highly probable that many of the budget studies did not even count the employee's contribution as saving. The understatement of pension savings is a general problem with cross-section data, and applies also to other cross-section data cited both for, and against, the permanent income theory. But at least in the United States, coverage by private pension systems does not seem to reduce the rate of saving apart from pensions substantially, and may even increase it slightly [3, pp. 51-52] [4]. Hence, if one is interested in saving other than saving via pension funds, one does not have to attach much importance to variations in pension fund coverage of different groups. Moreover, for one of the above-cited studies [3], separate data for covered and noncovered households are available and they reject the modified permanent income theory. No information is available on contractual savings other than pensions.

The final variable, subjective and cultural factors, is vague, and hence hard to analyze. Yet it should, at least, be mentioned since it *may* account for some of the differences in the propensities to consume of various occupations. Thus, it is possible that households with high permanent incomes save a relatively large percentage of their income, in part, because they are better educated and hence have more foresight. Similarly, households with a low permanent income may have a low saving-income ratio because they are less influenced by the "puritan ethic" than are wealthier households. But there is some evidence that the negative correlation of permanent income and the average propensity to consume cannot be due to differences in the psychology of social classes. If it were, one would not find it if one compares occupations comprised in the same broad social class. And a comparison of the average propensities to consume of skilled and unskilled workers

¹⁸ In particular, for those studies which compare white collar employees and manual workers, capital gains are presumably quite unimportant. Insofar as capital gains do occur among the groups covered in the above studies, capital gains (as a proportion of income) are probably positively correlated with permanent income. Hence, by excluding capital gains from income, but including consumption out of capital gains in consumption, the data probably raise the propensity to consume more for households with high permanent income than for households with a low permanent income. The direction of this bias is in favor of the modified permanent income theory [6, p. 693], and hence this factor too cannot be held responsible for the poor showing of the theory. For the prediction coefficient the direction of the bias is uncertain.

shows a significant negative correlation between permanent income and the average propensity to consume.¹⁹ Moreover, if the psychology of different income groups is really important, it is surprising that it has not been used in other consumption function studies, and I will therefore assume that I can ignore it here too. Admittedly, this assumption may be wrong, but if these cultural factors *are* important, much of the evidence favorable to the permanent income theory would have to be re-evaluated too.

There is some additional evidence that the results shown in Tables 1 and 2 do not represent merely the correlation of some other variable with permanent income and with the average propensity to consume. First, I have used budget studies for many countries over many years covering a wide variety of occupations. If the higher propensity to consume of the low permanent income groups were due to a factor other than income, it is not likely that this factor would be operative in nearly all of the studies. Second, I undertook a similar analysis covering only manual workers in the United States 1878-1900; it, too, rejects the permanent income theory²⁰ [22]. It is unlikely that any special factors which account for the negative correlation of permanent income and consumption when different broad occupational groups are considered would also account for the same result for relatively narrow occupational groups, all of them manual workers.

Hence, one may conclude that using the conventional definition of consumption, on the one hand, the permanent income theory is wrong in asserting that the marginal propensity to consume permanent income is equal to the average propensity. On the other hand, the theory does contain an important truth since the marginal propensity to consume *is* greater for permanent than for measured income. But the substitution of permanent income for measured income reduces the gap between the average and marginal propensities to consume only by about a third.²¹

¹⁹ There are twelve studies which provide data for skilled (or skilled and semiskilled) workers and for unskilled (or unskilled and service) workers. In eleven of these cases the unskilled workers have a higher average propensity to consume. This is significant at the one per cent level. (In one of these studies the difference between the two propensities to consume shows up only in the second decimal place. If one therefore leaves this study out the results are still significant at the one per cent level.)

²⁰ For these data the prediction coefficients (which are not given in the article) show a great variability and the median is, by a narrow margin, greater than zero, thus supporting the conventional theories. The difference between these two studies in this regard could be due to sampling fluctuations. In any case, the 19th century data are not as reliable as the ones used in this paper.

²¹ But note that this result is derived from a very simple consumption function. A more complex function which includes variables such as liquid assets which are likely to be partially proxies for permanent income would presumably show a smaller difference between the propensities to consume measured and permanent income.

FULL EMPLOYMENT POLICY AND ECONOMIC GROWTH

By RICHARD R. NELSON*

Within the context of a simple aggregative model, this paper explores how the rate of labor force growth and the rate of technical advance influence the fiscal and monetary policies needed to maintain equality of aggregate demand and potential output. The model attempts to tie together two strands of analysis that have developed in the literature—a neoclassical strand stemming from Solow's work on the determinants of growth of potential output and a neo-Keynesian strand stemming from the Harrod-Domar studies of the conditions under which full employment can be maintained in a growing economy [8] [9] [4] [1].¹

I. *The Basic Model*

The framework of the model is traditional. The supply of output at full employment (or potential output) is assumed to be a Cobb-Douglas function of capital and labor, given the level of technology. To simplify notation in subsequent calculations, and to facilitate generalization in the appendix, the production function will be written in a slightly unconventional form:

$$(1) \quad Q = K^{\alpha}(L \cdot A)^{1-\alpha},$$

where Q is potential output, K is the stock of capital, L is the labor supply and A an index of labor effectiveness. Technical progress is assumed to be purely labor augmenting. (In the Cobb-Douglas production function, labor augmenting technical progress and Hicks neutral technical progress are equivalent.) Thus the rate of growth of potential output is:²

*Any views expressed in this paper are those of the author. They should not be interpreted as reflecting the view of The RAND Corporation or the official opinion or policy of any of its governmental or private research sponsors.

The author is indebted to Benton Massell, Edmund Phelps, Hugh Rose, and Robert Solow for a number of useful comments and suggestions.

¹ There are a number of other treatments of this same general topic, the relationship between growth of potential output and the conditions required for full employment. Tobin [10] [11], Smith [7], Eisner [2], and Hall [3], in particular, have dealt with this question, but within the context of models that differ from the present one in significant respects.

² The more conventional formulation is:

$$Q = BK^{\alpha}L^{1-\alpha}, \quad \text{and} \quad \frac{\dot{Q}}{Q} = \frac{\dot{B}}{B} + \alpha \frac{\dot{K}}{K} + (1-\alpha) \frac{\dot{L}}{L}.$$

If $A = B^{1/(1-\alpha)}$, the two formulations, of course, are exactly equivalent.

$$(2) \quad \frac{Q}{Q} = \alpha \frac{K}{K} + (1 - \alpha) \left(\frac{L}{L} + \frac{A}{A} \right).$$

In the appendix to this paper a more general production function is used. While there are a number of important added complications, it is demonstrated there that many of the implications of the model employing a Cobb-Douglas production function carry over, with qualifications, when a more general neoclassical production function is employed, so long as it is assumed that technical progress is purely labor augmenting.

On the demand side, I ignore exports and imports and assume total effective demand is given by:

$$(3) \quad Y = C + G + I,$$

where Y is total demand and C , G , and I are consumption, government spending, and investment, respectively. Consumption is assumed to be a constant fraction of disposable income which in turn is equal to GNP minus taxes at a constant proportional tax rate, t . There are no business retained earnings or depreciation allowances. Government spending is a constant fraction, g , of GNP. Thus:

$$(4) \quad Y = c(Y - tY) + gY + I.$$

Defining $s = 1 - c$, this can be written in the familiar form:

$$(5) \quad Y = \frac{I}{s + t(1 - s) - g}.$$

The concept of "full employment" in equation (1) is a normative one relating to the socially optimal degree of labor utilization. In general the measured rate of unemployment will not be zero at "full employment" output, nor is this the maximum output that can be attained; however, if output is pushed (or pulled by demand) beyond this level there will be stronger inflationary pressures. Full employment output thus represents output at the degree of labor utilization the society deems optimal, balancing the benefits in terms of decreased unemployment and greater output that result as demand is increased, against the greater inflationary tendencies and, perhaps, higher unit costs, that also are a concomitant of greater pressure of demand on a given supply of labor and capital.^{2a}

^{2a} The relationship between output and increased labor force utilization need not, and in general will not, follow equation (1). One would expect average labor quality to decline as labor utilization rates increased. While in a situation where the economy was operating with capital being underutilized the decreased labor quality effect might be for a while be offset by more efficient operation of existing capital, we are concerned with sustained degrees of labor utilization, and it can be assumed that capital adjusts to that rate. Thus in the long-run production function with the (sustained) degree of labor utilization as a variable, output should be positively related to amount of employment but negative related to the degree of labor force utilization.

A principal objective of fiscal and monetary policy, then, is to adjust actual output so that it is equal to full employment output, neither lower with higher unemployment rates, nor higher with more rapid price increase. For this objective to be achieved, the demand for goods and supply of goods at full employment, Y and Q , must be equal over time.³ If we focus on a moment of time, say time t_0 , then the level of effective demand generated by investment through the multiplier will equal full employment output when:

$$(6) \quad I_0 = [s + \iota(1 - s) - g]Q_0.$$

For full employment to persist into the next moment of time:

$$(7) \quad \left(\frac{\dot{I}}{I}\right)_0 = \left(\frac{\dot{Q}}{Q}\right)_0.$$

These conditions of course do not imply that full employment will persist further. But under certain conditions \dot{I}/I and \dot{Q}/Q will be constants. If they are constants and if equations (6) and (7) hold initially, Y and Q will continue to be equal.

The key relationship in the model is the investment equation. Investment is both an important contributor to growth of potential output, and the principal dynamic determinant of the level of aggregate demand. I assume that the level of investment is determined by the volume of profitable opportunities to expand the capital stock. In this paper we are examining conditions that must hold for full employment (and full utilization of the capital stock) to be realized; if there is no slack, there will be profitable opportunities for new investment if the marginal productivity of capital (at full employment of labor) exceeds the interest rate.⁴ Indeed, at interest rate r there will be profitable investment opportunities so long as the actual capital stock falls short of K^* , the profit maximizing stock, where:⁵

³ I assume that, if the goods market is in balance at full employment, the labor market is also—that is, that the real wage rate is such that the demand for labor equals the full employment supply of labor when aggregate demand and supply of output are in balance.

⁴ There are, of course, two major qualifications to this. First, the correct statement of the conditions for expected profitability is that the expected discounted flow of future net returns exceeds the cost of new equipment. This involves a look into the future. The condition of excess of short-run marginal productivity over the existing interest rate is a proxy for the correct profitability conditions only under rather special circumstances. Second, under conditions of risk aversion or imperfect capital markets, the cutoff on investment decisions might occur at expected rates of return significantly higher than the interest rate.

⁵ K^* is derived by solving for K in the equation:

$$r = \frac{\partial O}{\partial K} = \alpha K^{(\alpha-1)} L^{(1-\alpha)} A^{(1-\alpha)}.$$

Again, it should be noted that I am assuming the wage rate is compatible with full employment

$$(8) \quad K^* = \left(\frac{\alpha}{r}\right)^{1/1-\alpha} L \cdot A.$$

The investment equation is:

$$(9) \quad I = \lambda(K^* - K),$$

or

$$(9a) \quad I = \lambda \left[\left(\frac{\alpha}{r}\right)^{1/1-\alpha} L \cdot A - K \right]$$

Thus the greater the opportunities for profitable expansion of the capital stock, the greater the rate of investment.

The dynamics of the model are provided by labor force growth and technical advance. Notice that these factors have two effects. First, both increase potential output. In the popular discussion of the problem of maintaining full employment it seems to be generally believed that the more rapid are technical progress and labor force growth, the greater is the difficulty in achieving an equal growth of demand. But, of course, a second effect of technical progress and labor force growth is to increase the size of the capital stock that is profitable at any given interest rate—and thus to spur investment and increase effective demand. (A third effect, then, is to further spur potential output through the increase in investment they stimulate.) If we take \dot{A}/A and \dot{L}/L as autonomous, and are free to vary r and t , under what values of r and t will the capacity-creating and demand-increasing effects of technical progress and labor force growth be equal? Is it true that if labor force growth or technical progress is more rapid, a more expansionary government policy is needed? These are the questions explored in the following sections.

Although these are Harrod-Domar type questions, the model presented here enables explicit recognition that the growth of the labor force and the advance of technology affect both the natural rate of growth (the growth of potential output) and the growth of investment; in the Harrod-Domar analysis the effect of these variables on investment demand is suppressed. The underlying model of growth of potential output follows Solow's neoclassical model. However, Solow does not work with explicit demand equations and hence cannot examine the conditions of sustained full employment; obviously this hinges on the

if the other conditions are met—that

$$\left. \begin{array}{l} \frac{\partial I}{\partial L} \\ \frac{\partial I}{\partial K} \end{array} \right| \begin{array}{l} = W \\ L = L \text{ full} \\ K = K^* \end{array}$$

assumed response of investors and savers to various conditions. Thus this model is a marriage of the two strands.

Before proceeding with the analysis it is important to make clear one important thing that the model does not try to do. The model says nothing about what happens if the dynamic equilibrium conditions are not met—if there is either excess demand or involuntary unemployment. There are two themes in the Harrod-type analysis—a statement of conditions of dynamic equilibrium, and a statement about what happens if there is excess capacity. The simple investment function used in this model could be enriched to take account of slack and of unfilled orders for new equipment, but I have not done this in the formal model. Also, the model contains no mechanism, explicit or implicit, to explain why the interest rate is what it is; it only attempts to say what the interest rate must be to be compatible with full employment, given the other variables of the system.⁶

II. *Full Employment Without Fiscal Policy*

Let us begin by assuming no government spending or taxes. Assume also that technical progress and labor force growth are proceeding at constant rates. The variable that is free is the interest rate. What is required of the interest rate if full employment is to be achieved and maintained?

Recalling the necessary conditions [equations (6) and (7)], the investment demand equation (9a), and the growth of potential output equation (2), the requirements for full employment to exist and persist into the next moment of time are:

$$(6a) \quad I(A, L, r, K) = sQ$$

$$(7a) \quad \frac{I_A A + I_L L + I_r r + I_K \dot{K}}{I} = \alpha \frac{\dot{K}}{K} + (1 - \alpha) \left(\frac{L}{L} + \frac{A}{A} \right).$$

If we ignore depreciation (which is treated in the appendix), the two equations are, of course, linked by the identity: $I = \dot{K}$. The relevant calculations are made in a footnote.⁷

⁶ Notice that the behavior equations of the model do not involve any wealth or financial variables explicitly. The model could be enriched to include these, as in the Tobin and Hall models. However, the benefits of the simple treatment used here are that certain important relationships stand out more strongly. Implicitly, something like the following is assumed with respect to financial and wealth variables. The allocation of accumulated consumer saving between money and claims on real assets is a function of the interest rate; however, the saving rate is not a function of either the interest rate or of wealth. The managers of business firms invest in new plant and equipment and pay for this by selling claims. The government finances its deficits by selling bonds whose rate of return is pegged to the rate of return on claims on real assets. The money price level is rigid.

⁷ The more explicit form of (6a) is:

One implication is that, under our assumptions, full employment will be compatible with a constant interest rate only if conditions are such that the capital stock and potential output are growing at the same rate. Or:

$$(10) \quad \frac{\dot{K}}{K} = \frac{Q}{Q} = \frac{L}{L} + \frac{A}{A}.$$

Since $\dot{K}/K = sQ/K$ (assuming full employment), the saving rate, the output-capital ratio, the growth of labor force, and the rate of advance of technology must be related as follows:

$$(11) \quad \frac{Q}{K} = \frac{1}{s} \left(\frac{L}{L} + \frac{A}{A} \right).$$

This "golden age" result was to be expected. Under the production function assumptions the rate of return on capital will rise or fall depending on whether the output-capital ratio is rising or falling. If Q/K initially falls short of (11), at investment equal to full employment saving, \dot{K}/K will fall short of \dot{Q}/Q and hence both the output-capital ratio and the rate of return on capital will rise. If Q/K exceeds (11), investment equal to full employment will lead to a fall in the output-capital ratio and the rate of return on capital. Under our investment assumption, such a rise or fall will lead to an increase or decrease in investment as a fraction of potential GNP, unless offset by a compensating change in the interest rate. Since saving is assumed to be a constant percentage of GNP, these compensating changes in r are then required for maintenance of equality between I and Q .

The system will asymptotically approach the golden age solution if \dot{L}/L , \dot{A}/A , and s remain constant. Let us now examine what this asymp-

$$(6b) \quad \lambda \left[\left(\frac{\alpha}{r} \right)^{1/(1-\alpha)} L \cdot A - K \right] = sQ.$$

Noting that $I = sQ$, the explicit form of (7a) is:

$$(7b) \quad \frac{\lambda \left[\left(\frac{\alpha}{r} \right)^{1/(1-\alpha)} L \cdot A \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} - \frac{1}{1-\alpha} \frac{\dot{r}}{r} \right) - \dot{K} \right]}{sQ} = \alpha \frac{\dot{K}}{K} (1-\alpha) \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} \right).$$

From (6b) we know that $\lambda[(\alpha/r)^{1/(1-\alpha)} L \cdot A] = \lambda K + sQ$. Substituting in (7b) and solving for \dot{r}/r :

$$\begin{aligned} \frac{\dot{r}}{r} &= - \left[\frac{sQ}{K} - \frac{\dot{L}}{L} + \frac{\dot{A}}{A} \right] (1-\alpha) \left[\frac{\lambda K + sQ}{\lambda K + sQ} \right], \\ \frac{\dot{r}}{r} &= - \left[\frac{1}{1-\alpha} \frac{\dot{K}}{K} - \frac{\dot{Q}}{Q} \right] (1-\alpha) \left[\frac{\lambda K + sQ}{\lambda K + sQ} \right]. \end{aligned}$$

Equation (10) follows by solving for the conditions under which $\dot{r}/r = 0$.

totically required interest rate is, and the variables on which it depends. Setting $\dot{r}=0$ and $Q/K=1/s(\dot{L}/L+\dot{A}/A)$ in equations (6a) and (7a) yields the following expression for the full employment interest rate in golden age equilibrium:⁸

$$(12) \quad r = \frac{\alpha}{s} \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} \right) \left[\frac{\lambda}{\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \lambda} \right]^{1-\alpha}.$$

If λ is very large the condition stated in equation (12) approaches:

$$(12a) \quad r = \frac{\alpha}{s} \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} \right).$$

For some purposes (12a) will be easier and more illuminating to work with.⁹

If the r of equation (12) prevails, the growth of potential output generated by \dot{L}/L and \dot{A}/A , and the growth of effective demand spurred by the impact of \dot{L}/L and \dot{A}/A on investment opportunities, will be in balance. Equation (12) can be interpreted as defining Wicksell's natural rate of interest—the interest rate at which investment demand and full employment saving are equal. Equation (12) also can be interpreted as defining the conditions under which the natural rate of growth will equal the warranted rate of growth in a Harrod-like formulation of the problem; if we work with (12a), $\dot{L}/L+\dot{A}/A$ clearly is the natural rate of

⁸ Manipulation of the Cobb-Douglas equation allows (6b) to be written:

$$(6c) \quad \lambda \left[\left(\frac{\alpha}{r} \frac{Q}{K} \right)^{1/(1-\alpha)} K - K \right] = sQ.$$

Dividing by K and noting equation (11) and that $\dot{K}/K=sQ/K$ we have the following triplet of equalities which define the conditions of sustained full employment in golden age equilibrium:

$$\frac{\dot{L}}{L} + \frac{\dot{A}}{A} = \lambda \left[\left(\frac{\alpha}{r} \frac{Q}{K} \right)^{1/(1-\alpha)} - 1 \right] = \frac{sQ}{K}.$$

Solving the first two for Q/K :

$$\frac{Q}{K} = \left[\frac{\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \lambda}{\lambda \left(\frac{\alpha}{r} \right)^{1/(1-\alpha)}} \right]^{1-\alpha}.$$

Noting that Q/K also must equal $1/s(\dot{L}/L+\dot{A}/A)$ and solving for r yields equation (12).

⁹ Of course (12a) could have been derived directly by assuming that the actual capital stock always equalled the profit-maximizing capital stock—there are never any unexploited investment opportunities—and working with an investment equation, $I=\dot{K}^*$. Tobin, in his 1964 *AER* paper [11], derives this equation by examining what will be the marginal productivity of capital in the golden age. Of course, this will be the *full employment compatible interest rate* only if it is assumed that $K=K^*$.

growth, equation (8) shows that the desired capital-output ratio, (K^*/Q) , equals α/r , and thus $s(r/\alpha)$ is the warranted rate of growth. If the actual and natural rates of interest are equal, then there will be equality of the natural and warranted rates of growth. An interest rate enters this formulation but not Harrod's because of the difference in investment functions. In this formulation, unlike Harrod's, there are a number of capital-output ratios that will satisfy businessmen, not just one, because the desired capital-output ratio is a function of the interest rate.¹⁰ If the interest rate is fixed and not a variable, the requirements for sustained full employment of this model are identical to Harrod's, despite a somewhat different investment demand equation and production function.¹¹

Equation (12) shows that given \dot{L}/L and \dot{A}/A , the interest rate compatible with full employment is negatively related to the saving rate. To balance a higher saving rate, investment must tap opportunities with a lower rate of return. Given the saving rate, the interest rate will be higher the faster the growth of the labor force, and the more rapid technological progress. While this last result may be surprising, the reason is obvious. Technological advance and labor force growth are the key factors determining the rate at which profitable investment opportunities grow and a given investment rate will yield a higher sustained rate of return when they proceed rapidly than when they are slow. If we treat r as fixed and s as a variable to be adjusted to match the investment-GNP ratio, then the result of faster technological progress or labor force growth would be an increase in the investment-GNP ratio (and a required increase in the saving rate), as equation (13) shows:

$$(13) \quad \frac{I}{Y} = \frac{\alpha}{r} \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} \right) \left[\frac{\lambda}{\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \lambda} \right]^{1-\alpha}.$$

This is a result clearly in the spirit of Schumpeter. But if the saving rate is fixed, with faster technical progress or labor force growth the interest rate must be increased to keep investment from outrunning full employment saving.

Thus, in this model at least, given any existing interest rate, an acceleration of technical progress or labor force growth provides even more of a spur to demand than to potential output. In a world where the

¹⁰ This, of course, has been the main bone of contention between Solow [10] and Tobin [8], on the one hand, and Harrod [4] on the other.

¹¹ Eisner makes the point that the Harrod rigidity of (or a ceiling on) the capital-output ratio can stem from either rigidity of the desired capital-output ratio, or from interest rate rigidity or an interest rate floor. If the elasticity of substitution were less than one, then a given change in the desired capital-output ratio would require a far larger change in the interest rate, and the floor interest rate might be hit at a quite low capital-output ratio.

interest rate adjusts up and down to equilibrate investment and full employment saving, this result would be of no particular significance. But if the interest rate is sticky, an acceleration of these forces will be reflected in decreased unemployment or inflationary pressures.

III. *The Requirements for Stabilization Policy*

Active stabilization policy may be required for two different reasons. First, in the absence of active policy it may be impossible to achieve the parameter values consistent with full employment; this might be the case, for example, if there is an interest rate floor. Second, even if the parameters can be achieved without active policy, tendencies of the system to move and stay at full employment may be weak. The concern about full employment generated by the early Harrod-Domar models involved both aspects—the required conditions appeared infeasible (in the absence of government deficit spending programs to reduce total saving as a fraction of GNP) and, in addition, full employment seemed a highly unstable equilibrium.

As pointed out earlier, the model above contains no analysis of the stability of the full employment path, nor will any formal analysis be presented here. However, the following brief discussion may help to put the problem in context.

Assume that when aggregate demand and potential output are not equal, the difference first shows up in unfilled orders or unintended inventory accumulation. Let us focus on the latter case of deficiency in aggregate demand. Assume that there are two kinds of reactions taken by business firms. First, they reduce investment expenditures; thus the basic investment equation must be modified by adding a term reflecting underutilization of existing capital. Second, they reduce production and income payments. They may or may not lay off workers or cut back on new hires—if they do not, they reduce hours and, in any case, incomes are reduced in line with cutbacks in output. Consumption then will fall.

Thus in this model, there may be present the type of instability discussed by Harrod despite strictly neoclassical investment and production assumptions. The sensitivity of investment and output decisions to the accumulation of inventories is a strong destabilizing force. To the extent that the interest rate rises or falls depending on the difference between the existing level of investment and full employment saving, this is a stabilizing force. However, one would expect that, even if the interest rate adjusts relatively quickly, the short-term sensitivity of the desired capital-output ratio to the interest rate might be much smaller than the long-term sensitivity as given by equation (7).¹²

¹² In the limit with no short-run sensitivity of the desired capital-output ratio to the interest

The extent to which active stabilization policy is required depends on the balance between the destabilizing effects of accumulating inventories and growing underutilization of capacity, and the stabilizing effects of interest rate adjustments. In the following discussion it will be assumed that conscious policy actions are required at least from time to time to keep aggregate demand and potential output in balance.

Let us now introduce the government sector and government stabilization policy into the model. If the income tax rate is t , and government expenditures as a fraction of GNP are g , then the conditions of full employment in the steady state are:¹³

$$(12b) \quad r = \left(\frac{\alpha}{s + t(1-s) - g} \right) \left(\frac{L}{L} + \frac{A}{A} \right) \left(\frac{\lambda}{\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \lambda} \right)^{1-\alpha},$$

(12a) becomes

$$(12c) \quad r = \left(\frac{\alpha}{s + t(1-s) - g} \right) \left(\frac{L}{L} + \frac{A}{A} \right).$$

For given values of s , g , \dot{L}/L , \dot{A}/A , and λ , this equation enables us to trace out the alternative pairs of r and t that are consistent with full employment in a golden age.¹⁴ The curve is a rectangular hyperbola, as shown in Figure 1, which will shift to the right or left depending on the strength of the other factors that determine demand.

Note that, with fiscal policy now admissible, the previous results regarding the interest rate compatible with full employment are generalized as follows: the faster are technical progress or labor force growth, the tighter must be stabilization policy. This statement applies to the steady state in which $\dot{K}/K = \dot{Q}/Q$ and a constant r and t are com-

rate, and strong sensitivity of investment to the degree of slack, we have an accelerator investment demand equation rather than the long-run neoclassical one of this paper. The investment demand equation of this paper would appear to make behavioral sense only a world in which government policy, or natural stability, is strong enough so that business firms assume slack to be temporary.

$$(6c) \quad \lambda \left[\left(\frac{\alpha}{r} \right)^{1/(1-\alpha)} L \cdot A - K \right] = [s + t(1-s) - g]Q,$$

and

$$(7c) \quad \frac{\left[\lambda \left(\frac{\alpha}{r} \right)^{1/(1-\alpha)} L \left(\frac{L}{L} + \frac{A}{A} \right) - \dot{K} \right]}{[s + t(1-s) - g]Q} = \alpha \frac{\dot{K}}{K} + (1-\alpha) \left(\frac{L}{L} + \frac{A}{A} \right).$$

Only the constant before Q in equations (6) and (7) has been changed. Equation (12b) follows.

¹⁴ The results here are very similar to those of Smith [7] and of Musgrave [5]. However, the investment equation in this model is explicitly dynamic.

FIGURE 1.
Alternative t, r pairs consistent with equality of Q and Y .

patible with sustained full employment. Assume that we are on one long-run equilibrium time path and that, suddenly, the rates of technical progress or the rate of growth of the labor force rises. What is required of policy?

One possibility is to shift immediately to the new steady state path through fiscal policy. In the new steady state \dot{K}/K must rise to equal the now increased $\dot{L}/L + \dot{A}/A$; thus room must be made for a higher ratio of investment to GNP through increased taxes so that $[s + t(1 - s) - g]Q/K = \dot{L}/L + \dot{A}/A$ at the new higher level. If λ is infinite, investment will rise to the needed higher fraction of potential GNP at the old interest rate. If λ is not infinite, equation (12b) shows that some reduction in the interest rate will be required. Once these changes in the tax and interest rates are made, the system is on a golden age path again, with a higher investment-GNP ratio.

Another possibility is to stress monetary policy and to respond more gradually. Taxes can be maintained and the interest rate tightened to keep investment demand from rising as a fraction of potential GNP. With technical advance now more rapid, and the interest rate increased to keep investment at the same fraction of GNP, the rate of growth of the capital stock will be faster than it was because GNP will be growing faster. But it will not immediately rise to equal the faster rate of growth of potential output. Therefore the capital-output ratio will gradually fall toward its new (lower) steady state equilibrium. And as it falls, the

rising marginal productivity of capital will require further increases in the interest rate. Eventually the new equilibrium will be reached.

The fact that these choices are open to the government means that full employment policy and growth policy cannot be separated; the target degree of labor utilization can be achieved through different alternative policies which have different effects on present consumption and future output. The golden rule for golden age advocates would keep the investment—GNP ratio constant and equal to capital's share of GNP, and vary the interest rate up or down following variations in $\dot{L}/L + \dot{A}/A$. Those who believe in a constant social rate of time preference would keep r constant and at that rate, and permit I/GNP to rise or fall with $\dot{L}/L + \dot{A}/A$, varying the tax rate to make room.

Returning to the steady state conditions, an interesting question is: under what conditions will full employment be consistent with a government surplus? For simplicity we will use equation (12c). Rearranging:

$$t - g = \frac{\alpha}{r} \left(\frac{L}{L} + \frac{A}{A} \right) - s + st.$$

Letting $S^* = t - g$ be the government surplus as a fraction of potential GNP:

$$(14) \quad S^* = \frac{\frac{\alpha}{r} \left(\frac{L}{L} + \frac{A}{A} \right) - s + sg}{1 - s}.$$

Equation (14) shows some familiar results. The balanced budget multiplier requires the surplus at full employment without inflation to be larger (or the deficit smaller) as government spending increases as a function of potential GNP. And obviously the surplus must be larger, or the deficit smaller, the looser is monetary policy. The new result is that, given g and r , the faster technical progress and labor force growth, the greater will be the surplus or the smaller the deficit needed to keep Q and Y in line.¹⁵ In a very real sense the higher tax rates required when technological change is rapid should be viewed as the price we have to pay to achieve rapid growth without inflation. But if there are pressures against increasing government spending as a percentage of GNP, if there exist strong political pressures against running sustained budget deficits, and if there is a floor to the interest rate, rapid technical progress, far from being a threat to full employment, may be a prerequisite for it.

¹⁵ Here the ignoring of the effect of financial wealth and liquidity is important. Obviously the size and sign of the deficit has an effect on the economy through these variables as well as through disposable income.

APPENDIX

If we assume that the capital stock depreciates at rate δ , this affects the basic equations in two ways. First, at the profit maximizing capital stock, the marginal productivity of capital is equated to $r + \delta$, not r . Second, the rate of growth of the capital stock is equal to $sQ/K - \delta$, not sQ/K . This affects the conclusions in the following ways. First, the golden age output-capital ratio is

$$\frac{Q}{K} = \frac{1}{s} \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \delta \right).$$

Second, the golden age interest rate is

$$r = \frac{\alpha}{s} \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \delta \right) \left[\frac{\lambda}{\frac{\dot{L}}{L} + \frac{\dot{A}}{A} + \lambda + \delta} \right]^{1-\alpha} - \delta.$$

Thus the qualitative conclusions change in no essential way.

Relaxing the Cobb-Douglas assumption raises a number of complications. In particular Hicks neutral technical progress no longer is necessarily equivalent to labor augmenting technical advance, and further there may be upper or lower bounds on the output-capital ratio which preclude equality of the rate of growth of the capital stock and the "augmented" labor force for certain values of s , \dot{L}/L , and \dot{A}/A . However, assuming technical progress is labor augmenting and that a golden age (with a positive elasticity of output with respect to labor) is possible within the domain of interest, the qualitative results apply to a model with a more general neo-classical production function.

The production function can be written in the more general form

$$Q = F(K, L \cdot A).$$

Assuming technical progress is labor augmenting:

$$\frac{Q}{Q} = \left[\frac{F_K K}{Q} \right] \frac{\dot{K}}{K} + \left[\frac{F_{LA} L \cdot A}{Q} \right] \left(\frac{\dot{L}}{L} + \frac{\dot{A}}{A} \right).$$

If $F(\cdot)$ has the standard neoclassical properties and there is perfect competition, the terms in brackets will be the shares of capital and labor, respectively. Investment will be profitable up to the point where $F_K(K, L \cdot A) = r$. Under our assumptions this is equivalent to $F_K(K/L \cdot A, 1) = r$. The profit-maximizing capital stock is $K^* = F_K^{-1}(r) \cdot L \cdot A$. Notice that the forms of these more general equations are very similar to the Cobb-Douglas special cases.

The conclusions of the model would appear to depend strongly on the existence of a stable golden age equilibrium where $sQ/K = \dot{L}/L + \dot{A}/A$. With a Cobb-Douglas function Q/K increases without finite upper bound as $L \cdot A/K$ increases, and declines toward zero as $K/L \cdot A$ increases; thus there is a Q/K which can satisfy the golden age equation for any positive

values of s , \dot{L}/L , and \dot{A}/A . This does not apply generally; for certain neo-classical production functions Q/K may be bounded above as $L \cdot A/K$ increases, or approach a positive lower bound as $K/L \cdot A$ increases.

So long as we are considering values of $1/s(\dot{L}/L + \dot{A}/A)$ which do not fall outside the bounds of Q/K , the qualitative conclusions regarding the relationship of $\dot{L} + \dot{A}/A$ to the full employment interest rate carry over to this more general formulation. Within this range at least, the marginal productivity of capital is an increasing function of $Q/K = h(L \cdot A/K)$, and the higher the marginal productivity of capital the higher must be the interest rate required to keep investment demand equal to full employment saving (given the investment and saving assumptions of the model). This result does not depend on the sign or size of the elasticity of substitution, although the quantitative sensitivity of r to \dot{L}/L and \dot{A}/A will depend on the exact shape of the isoquant. Further, it is interesting to note that, for the case where the elasticity of substitution is less than one, labor's share will tend to be smaller in the full employment equilibrium when technical change and labor force growth are rapid than when they are slow; the opposite holds if the elasticity of substitution exceeds one.

However, if the elasticity of substitution is less than one, it is possible that at very rapid rates of growth of labor or technical advance, it will be impossible to achieve a golden age equilibrium with capital and "augmented" labor growing at the same rate. For as Q/K and $L \cdot A/K$ increase, the elasticity of output with respect to labor will fall, and it may fall to zero before Q/K can equal $\dot{L}/L + \dot{A}/A/s$. In this case asymptotically \dot{Q}/Q and \dot{K}/K will grow at the same pace but slower than $\dot{L}/L + \dot{A}/A$. A related problem happens when the elasticity of substitution is greater than one, and $\dot{L}/L + \dot{A}/A$ is small. (For an excellent discussion, see Pitchford [6].)

If s and $\dot{L}/L + \dot{A}/A$ take on values such that either of these conditions occurs, the analysis becomes quite complicated, depending on the exact form of the production function. Historically, however, we have not come close to experiencing situations where labor's share of national income was driven close to zero. If the rest of the assumptions of the model do not strain reality too much, the limitation that the model only applies to a particular range of s , \dot{L}/L , and \dot{A}/A [the range depending on $F(\cdot)$] does not appear to detract from any heuristic value it might have.

THE HECKSCHER-OHLIN THEOREM, THE LEONTIEF PARADOX, AND PATTERNS OF ECONOMIC GROWTH

By NOBUO MINABE*

The core of the Heckscher-Ohlin theorem of the nature of trade patterns [6] [15] is the explanation of the relation between factor endowments and the doctrine of comparative costs (or commodity price ratios). The theorem asserts that a country exports those commodities produced with relatively large amounts of the country's relatively abundant factor. Thus a capital rich country exports capital intensive products. Leontief [13] applied the theorem to upset the popular notion that the United States exports capital intensive commodities. Leontief's input-output data show that America imports capital intensive commodities compared with American export goods. Heckscher defined relative factor abundance by the pre-trade ratio of factor prices in the two countries. By definition capital is relatively cheaper in the capital rich country before trade. On the other hand, Ohlin and Jones [10] introduced an alternative definition of relative factor abundance, which is related to the physical endowments of the factors of production in each country. According to the definition a country is relatively capital abundant if, and only if, it is endowed with a higher proportion of capital to labor than the other country. By using the revised definition, they have demonstrated that a bias on the supply side, due to differences in (physical) factor endowments between the two countries, may be offset by differences in the community taste patterns between countries. The other reason for the Leontief paradox, which has been given by Jones and later Johnson [8], is the case of factor intensity reversals. A commodity, F , is capital intensive for a factor price ratio when it employs a higher capital/labor ratio than the other commodity, M . However, assuming constant-return production functions it is quite possible that F is capital intensive for some set of factor price ratios and labor intensive for some other set, so the capital/labor ratios employed in the two commodities must be equal for some factor price ratio. When the factor endowment ratios of the two countries lie on opposite sides of the common capital/labor ratio, there is no unique relation between factor endowment and commodity price ra-

* The author is associate professor in economics in Osaka City University. In preparing this article I have benefited by conversations with Professor Ronald W. Jones. I am also grateful to the referee of this paper for thoughtful criticisms and useful comments.

tios. If the Leontief paradox occurs because of factor intensity reversals between the two industries, factor prices can never be equalized between the two countries. On the other hand, I mentioned [14] that if the Leontief paradox occurs without assuming the existence of factor intensity reversals under the condition of the same production functions in the two countries, then factor price equalization must hold. This condition is equivalent to a sufficient condition for incomplete specialization. The law of factor price equalization proved by Samuelson [17] asserts that there is a continuous one-to-one correspondence between goods and factor prices when two different countries have the same production functions and produce all the commodities. Incomplete specialization is necessary for the law, and the incomplete specialization of both countries is possible (but not inevitable, for much depends on demand) if endowment ratios of different countries are very close. The Stolper-Samuelson theorem [19] asserts that if a price of a commodity rises, the real rental to the corresponding "intensive" factor will increase. Assuming no intensity reversals and identical production functions without specialization, the Stolper-Samuelson theorem implies factor price equalization because the former demonstrates the existence of a unique magnification effect of a rise in the commodity price on the corresponding intensive factor price.¹ The Rybczynski theorem [16] bears a dual relation to the Stolper-Samuelson theorem, as has been pointed out by Jones [11]. Rybczynski analyzes the effect on absolute levels of outputs of changes in the endowment of one factor at unchanged commodity prices; namely, that a rise in the endowment of one factor will bring about a more than proportionate rise in the output of the commodity which is intensive in the factor in question, while it will decrease the output of the other commodity at a constant commodity price ratio. On the other hand, the Heckscher-Ohlin theory of the nature of trade patterns revised by Jones [10] examines the ratio of outputs to be determined by ratios of factor endowments at a constant commodity price ratio. In other words, the Heckscher-Ohlin theory asserts the existence of a one-to-one correspondence between output ratios and the factor endowment ratios, while the Rybczynski effect asserts the existence of a special kind of relation between the factor endowments and outputs. Leontief [13] himself explains the "Leontief paradox" by differences in labor qualities in the two countries. Qualities of (physical) capital may differ in the two countries, too. Differences in labor and capital qualities may be theoretically translated into differences in production func-

¹ This is true even when the number of commodities and that of factors increases if we define the Stolper-Samuelson theorem in the strong form, i.e., all the nonintensive factor's real income to be decreased. See Chipman [3].

tions or in technology with the same qualities of labor and capital in the two countries. The traditional Heckscher-Ohlin theory assumes identical production functions in the two countries. But technological conditions may differ in the two countries. In these cases, commodity prices differ in the two countries at common factor prices and factor endowment ratios. In other words, a capital rich country may export labor intensive goods. The law of factor price equalization never holds in these cases because the real factor rewards must not be the same in the two countries. Only in a special case of technical progress in the two industries, the relative (but not real) factor prices are equalized after trade.

The paper falls into three parts, and the model used is the Heckscher-Ohlin type of two factors and two commodities based on the analysis of comparative statics. First, in order to isolate the core of the Heckscher-Ohlin theory of the nature of trade, I will assume that the two countries have the same production function in each industry and also have the same community taste patterns. Assuming no factor intensity reversals, the two countries differ only in their factor endowments. We will consider the effect on the transformation curve of changes in factor endowments. Second, I abandon the assumption of identical production functions in order to analyze the relation between technological changes and the transformation curve in the two-sector model. Finally, I will consider new conditions under which the Leontief paradox occurs and/or conditions for the Heckscher-Ohlin theory. In the process of economic growth, the trade pattern may change alternately between the two countries.

Thus our discussion will be done in the following order. The core of the Heckscher-Ohlin theory demonstrates the existence of a unique relation between the factor endowment ratio and the shape of the transformation curve assuming identical production functions in the two countries. The output ratio of the capital intensive commodity would be higher in the capital abundant country than in the labor abundant country at a common factor (and commodity) price ratio. When we relax the assumption of identical production functions in the two countries, the Leontief paradox is possible (not inevitable, for much depends on demand) if the price of the capital intensive commodity is cheaper in the labor abundant country than in the capital abundant country at a common factor price ratio. To close the production model I assume that community taste patterns are the same in the two countries. The relation of the closed economy commodity price ratios between the two countries depends upon demand conditions as well as factor endowment ratios and technological conditions. If the two countries have identical taste patterns, the Leontief paradox may occur by

FIGURE 1

technological progress. Whether the Heckscher-Ohlin theory holds or not depends upon not only physical factor endowment ratios but also patterns of economic growth when the two countries have different production functions. We can easily relax the assumption of identical taste patterns in the two countries with a minor modification.

I. *Factor Endowments and Transformation Curves*

There are two commodities, manufactured goods, M , and food, F . The production function of each industry is identical and homogeneous of the first degree in the two countries, America, A , and Britain, B . Manufactured goods are assumed to be labor (L) intensive and food to be capital (K) intensive for any wage/rental ratio. Countries A and B have identical community taste patterns, but are endowed with different ratios of the two factors of production, L and K . We assume country A is endowed with a higher proportion of capital to labor than country B . That is,

$$(K/L)_A > (K/L)_B$$

Let us consider Figure 1. The two axes show respectively labor and capital, and unit isoquants, M and F , are drawn, where unit isoquants are loci of all possible combinations of two factors to produce one unit of each commodity. For a given factor price ratio of the slope of CD , the M -line and the F -line represent the factor intensities of the two

FIGURE 2

commodities at the competitive equilibrium situation. The point A represents country A 's factor endowments, and the ray λ is country A 's capital/labor endowment ratio. Assume country B 's endowments lie at some point along the ray ρ . The outputs of manufactured goods and food are represented by the length of OG/Og and OE/Oe by drawing the lines from A parallel to the M -line and the F -line. By extending those parallel lines, the whole area below the ray λ can be divided into the three parts, which are represented by angles α , β and γ .

The Rybczynski theorem [16] asserts that, if country B 's factor endowments lie at some point on the horizontal line from point A (for instance, B_1), country B produces more manufactured goods and less food than country A does at a constant factor price ratio. This theorem can be generalized as follows: if country B 's factor endowments belong to any point inside the angle α , country B produces more manufactured goods and less food than country A does at a constant factor price ratio. But when country B 's factor endowments lie in the angle β or γ , country B produces respectively more or less of both goods than country A does at a constant factor price ratio. Those relations can be seen by comparing the outputs corresponding to three points B_1 , B_2 , and B_3 , all of which lie along the ray ρ . Those outputs are read off by completing the parallelograms at B_1 , B_2 , and B_3 .

Figure 1 can be translated into Figure 2. Curve $A'A'$ represents country A 's transformation curve, and the point a is the corresponding outputs of the point A in Figure 1. Ray λ' shows country A 's output ratio (O_F/O_M) at the factor price ratio of slope CD of Figure 1. As

country *A* is endowed with a higher proportion of capital to labor than country *B*, country *B*'s outputs will never lie at any point above the ray λ' at a constant factor price ratio. Furthermore, we can say that when country *B*'s endowments lie at any point along the ray ρ of Figure 1, the corresponding output must be located at some point along the same ray, say, the ray ρ' of Figure 2. The slope of the ray ρ' must be smaller than that of the ray λ' . Notice that, assuming the three points b_1 , b_2 , and b_3 to be the corresponding outputs to points B_1 , B_2 , and B_3 of Figure 1 at a constant factor price ratio, country *B*'s transformation curve would have respectively the same slope at those points, which is also the same as that of country *A*'s transformation curve at the point *a*. They differ only in scale, and the ratio of $Ob_3 : Ob_1 : Ob_2$ of Figure 2 must be equal to that of $OB_3 : OB_1 : OB_2$ of Figure 1.

The shape of the transformation curve depends upon the technology and factor endowment ratios, while the scale of the transformation curve is determined by quantities of the two factors. We have three cases: (1) when country *B*'s factor endowments lie at any point inside the angle α of Figure 1, the corresponding outputs of country *B* must lie at some point inside the angle α' of Figure 2; (2) when the former lie at any point inside the angle β of Figure 1, the latter must lie at some point inside the angle β' of Figure 2; and (3) when country *B*'s factor endowments lie at any point inside the angle γ of Figure 1, the corresponding outputs must lie at some point inside the angle γ' of Figure 2 at a constant factor price ratio.

We have analyzed the relation between the factor endowments and the outputs at a constant factor price ratio. Notice that, whenever the factor endowment ratio is given, the shape of the transformation curve is uniquely determined independently of the scale of production, which depends upon the quantities of the two factors. There is a unique relation between the factor endowment ratio and the shape of the transformation curve. This is the core of the Heckscher-Ohlin theory.

II. *Technological Conditions and Transformation Curves*

We have mentioned that the Heckscher-Ohlin theory guaranteed a unique relation between the output ratio associated with the corresponding commodity prices and the factor endowment ratio at a given factor price ratio. It implies that the Heckscher-Ohlin theory is a dual of the theory of factor price equalization, which proves a unique relation between the factor and commodity price ratios at a given factor endowment ratio assuming incomplete specialization with identical production functions in the two countries. In this section, I will aban-

don the assumption of identical production functions in the two countries. That is, we will consider the effect on the transformation curve of technical progress in the two industries. Analysis of the effect of the economic expansion caused by technological progress may be pursued in two alternative ways. One is by analyzing new outputs that will result from changes of commodity price ratios caused by technical progress in the two industries at the initial factor price ratio. The other is by considering the effect on the outputs of economic expansion caused by technical progress in the two industries at a constant commodity price ratio. The latter approach may be applicable when the economy is small compared with the rest of the world, and the economic expansion does not affect the terms of trade. The second approach has been traditionally used (for instance [9]) since R. Findlay and H. Grubert [4] neatly developed the technique for dealing with biased technical progress, while in this section I will use the first approach.

Let us consider Figure 3, which is essentially the same as Figure 1. We assume as before that country *A* is endowed with a higher proportion of capital to labor than country *B*. Suppose technical progress occurs in country *B*'s *F* industry. Technical progress can be expressed by an inward shift of the unit *F*-isoquant curve. There are several types

of technical progress: Hicksian neutral, capital saving, and labor saving. On the other hand, it has been said [2] that technical progress has two effects, "cost-reducing" and "factor-saving," though our definition slightly differs from them (see Jones [12, p. 569, n.21]).

1. When Hicksian neutral technical progress [7] occurs in the F industry, F isoquants are scaled down so that, for instance, the unit F isoquant shifts to F' which is tangent to line $C'D'$, and parallel to line CD , at the point t along the F -line. The relative price of F must fall at a constant factor price ratio (which is the "cost-reducing" effect). On the other hand, the output of F rises from OE/Oe to OE/Ot , and that of M does not change at a constant factor price ratio. That is, Hicksian neutral technical progress in the F industry has the same effect on outputs as would an increase of the factor endowments from B to a certain point B' along the ray GB at a constant factor price ratio. The point B' is obtained by taking a point E' along the F -line such that $OE/Ot = OE'/Oe$ and constructing a parallelogram $E'EBB'$ (which is the factor-saving effect).

2. The given extent² of Hicksian capital-saving technical progress in the F industry would be represented by an inward shift of the unit F -isoquant such that it is tangent to line $C'D'$, at some point below t . Hicksian capital-saving technical progress in the F industry has the same effect on outputs as would an increase of the factor endowments from B into cone α at a constant factor price ratio.

3. The given extent of Hicksian labor-saving technical progress in the F industry would be represented by an inward shift of the unit F isoquant so that it is tangent to the line $C'D'$ at some point above t . In this case, the output of M always rises but that of F may decrease at a constant factor price ratio in spite of technical progress in the F industry. That is, the "factor-saving" effect has the same effect on outputs as would a change of factor endowments into the cone β at a constant factor price ratio. The critical case is such that the labor-saving technical progress in the F industry makes the unit F isoquant shift so as to be tangent to the line $C'D'$ at the point h , which is obtained by drawing a line through the point e parallel to the M -line so the output of F does not change (note that $Oh'/Oh = OE/Oe$). When the new unit F -isoquant is tangent to line $C'D'$ above the point h , the output of F must decrease at a constant factor price ratio. If outputs of both commodities are to increase at a constant factor price ratio, technical progress must occur such that the unit F isoquant is tangent to $C'D'$ on the segment ht in the cone γ . As a special case of this, if the unit F isoquant is

² The extent of technical progress in an industry is defined by a percentage fall in the relative price of the commodity at a constant factor price ratio, assuming no technical change in the other industry.

tangent to line $C'D'$ at the point q , which is derived by drawing a line through the point e parallel to the vector of factor endowments OB , outputs of the two commodities increase proportionally at a constant factor price ratio. Thus Hicksian neutral technical progress in one industry does not imply the neutral expansion of factor endowments. Other interesting cases may be an inward shift of the unit F isoquant along the horizontal or the vertical lines through the point e . The "factor-saving" effects are the same as the initial case of the Rybczynski effect in those cases: namely, one of the factor endowments increases without any change of the other.

If there are identical taste patterns in the two countries, the Leontief paradox is possible when the price of the capital intensive commodity is cheaper in the labor abundant country than in the capital abundant country at a common factor price ratio. In this sense the relatively labor abundant country has a production bias in favor of the capital intensive commodity in the case of the Leontief paradox. On the other hand, if we relax the assumption of identical production functions in the two countries, the Heckscher-Ohlin theory is possible when the price of the capital intensive commodity is cheaper in the capital abundant country than in the labor abundant country at a common factor price ratio. In this sense the relatively capital abundant country has a production bias in favor of the capital intensive commodity as in the traditional Heckscher-Ohlin theory.³ However, whenever the technology differs in the two countries, the law of factor price equalization never holds, because real factor prices must be different in the two countries after trade.

We have analyzed the effect on outputs and commodity price ratios of technical progress in one industry at a constant factor price ratio. Suppose technical progress takes place also in the M industry. The new unit M isoquant may (i) still lie outside line $C'D'$, (ii) be tangent to line $C'D'$, or (iii) cut line $C'D'$. In case (i) the relative price of F must decrease at a constant factor price ratio. In case (ii) it does not change, and in case (iii) it must rise at a constant factor price ratio. Clearly it is only in case (iii) that the Heckscher-Ohlin theory of trade patterns holds at a common factor price ratio in the two countries. Furthermore for each case there are Hicksian neutral, capital-saving, and labor-saving technical progress in the M industry too. There are several combinations of technical progress in the two industries.

³ In the above examples, the price of the capital intensive commodity, F , is cheaper in the labor abundant country, B , than in the capital abundant country, A , at a common factor price ratio. On the other other hand, if country B were endowed with a higher proportion of capital to labor than country A , the Heckscher-Ohlin theory would still hold.

Let us consider case (ii). It is only in case (ii) that both goods can continue to be produced at a constant factor price ratio without any change in the commodity price ratio. That is, the "cost-reducing" effects have cancelled each other out in the two industries so that the relative commodity price does not change. This case may be called the "neutral industry effect."⁴ Similarly cases (i) and (iii) may be called respectively *F*- and *M*-industry biased technical progress. The "differential industry effect"⁵ depends only upon the extent of relative technical progress in the two industries. When it is neutral, the relation between commodity and factor price ratios is the same as it would be in the case of no technical progress.

But changes in outputs depend not only upon the extent but also upon the nature of technical progress. Assume a given extent of Hicksian neutral technical progress in the *F* industry. (1) One critical case is such that the new unit *M* isoquant shifts to the point *j* derived by drawing a line *gj* parallel to the *F*-line.⁶ Outputs of *M* must decrease when the unit *M* isoquant shifts to any point below the point *j* at a constant factor price ratio in spite of technical progress. The "factor-saving" effect is represented by a change in factor endowments into the cone α . If outputs of both commodities are to increase at a constant factor price ratio, technical progress must occur such that the new unit *M* isoquant shifts to a point above *j*. (2) When the new unit *M* isoquant is tangent to line *C'D'* at the point *s* along the *M*-line, the technical progress is Hicksian neutral. In this case, outputs of both commodities increase proportionally at a constant factor price ratio without any change of commodity prices. The "factor-saving" effect can be represented by a shift of factor endowments from *B* to *B''* which is located along the ray *OB*. The transformation curve expands its scale with the same degree in the two industries, as in Figure 2. Notice that Hicksian neutral technological progress in every industry does not necessarily increase the outputs of all the commodities by the same proportion at a constant commodity price ratio unless the two industries have the same degree of technical progress. That is, the economic expansion is neutral only when the new unit *M* isoquant is scaled down to the point *s* on the line *C'D'*. On the other hand, when it shifts down to some point above (below) the point *s* on the line *C'D'*, the "scale-line" which is the loci of the economic expansion at a constant commodity price ratio is *M*-biased (*F*-biased).

⁴ The "neutral industry effect" seems to be essentially the same as Leontief's "comparative technological parity" [13, p. 344], at least marginally.

⁵ The name has been given first by Jones [12, p. 569]. See also Amano [1, p. 393].

⁶ The point *j* corresponds to the point *h* in the *F* industry.

Notice that, when the "differential industry effect" is neutral, the effect on outputs of technical progress is the same as in the case of changes in factor endowments, which has been discussed in section I. When Hicksian neutral technical progress occurs in the F industry and the differential industry effect is neutral, the economic expansion (or the scale of the economy) is neutral, M -biased, or F -biased depending on respectively Hicksian neutral, labor-saving, and capital-saving technical progress in the M industry. However, whenever Hicksian neutral technical progress occurs to the same degree in the two industries, the modified factor price equalization theory holds in the sense that the relative (but not real) factor prices must be the same in the two countries after trade (provided that specialization is incomplete). This is because the relation of product price ratios and ratios of factor reward is completely the same in these cases as it would be in the case of identical production functions in the two countries.

So far, we assumed that the degree of technical progress was the same in the two industries [case (ii)]. We can analyze similarly cases of biased industrial technological progress in the two industries [case (i) and (ii)], which in turn will be combined respectively with Hicksian neutral and biased technical progress in each industry. We still assume Hicksian neutral technical progress in the F industry.

1. When the differential industry effect is M -biased, the scale of the economy will expand in favor of M (that is, M -biased economic expansion) even in the case of Hicksian neutral technical progress in the M industry too. This is true also in the case of Hicksian labor-saving technical progress in the M industry. But when technical progress is capital saving in the M industry, the economic expansion might be F -biased.

2. When the differential industry effect is F -biased, the economic expansion is F -biased even in the case of Hicksian neutral technical progress in the two industries. This is true also in the case of Hicksian capital-saving technical progress in the M industry. When technical progress is Hicksian labor-saving in the M industry, the economic expansion might be F -biased. Whenever the differential industry effect is not neutral, the "cost-reducing effect" appears explicitly so that factor price equalization never holds even in the modified form.

III. *The Heckscher-Ohlin Theorem and the Leontief Paradox*

To close the production model, I assume that community indifference curves are the same in the two countries in order to clarify our argument.⁷ On the other hand, Gorman [5] has proved that there is a unique set of community indifference curves if, and only if,

⁷ I will relax the assumption later.

the Engel curves for different individuals at the same prices are parallel straight lines. Along the Engel curves the direction normal to the corresponding personal indifference locus will be parallel to the fixed direction.⁸ Clearly tastes of different individuals may be different, but an extra unit of purchasing power should be spent in the same way no matter to whom it is given under the necessary and sufficient condition quoted above.

The shape of the transformation curve is determined by the technology as well as the factor endowment ratio. When technological conditions are given in the two industries, the shape of the transformation curve depends on the factor endowment ratio. On the other hand, when the factor endowment ratio is given, the shape of the transformation curve is determined by the nature of technical change Hicksian neutral, capital-saving, and labor-saving technical progress under the condition of the given differential industry effect of technical progress. The differential industry effect which is determined by the relative extent of technical progress in the two industries will change the shape of the transformation curve so that it pulls out the transformation curve in a certain direction. For instance, when Hicksian neutral technical progress occurs only in the M industry (F industry), the transformation curve expands to the horizontal (vertical) direction in Figure 2. If Hicksian neutral technical progress occurs to the same degree in the two industries, the transformation curve is scaled out to the same degree in all directions.

Furthermore, notice that if the shape of the transformation curve is given, the closed economy commodity price ratios depend on the scale of the economy as well as on demand conditions whenever community taste patterns are not homothetic. In Figure 4, the straight line, OaT , which is an Engel curve, is derived from homothetic community indifference curves. In this case, the income elasticity of demand is unity. If the Engel curve is RaT' , the income elasticity of demand for manufactured goods is less than unity; the demand expansion is biased against manufactured goods. If it is aQT'' , the income elasticity of demand for manufactured goods is greater than unity. Suppose the shapes of the two countries' transformation curves are the same, but country B 's scale of the economy is greater than country A 's by neutral industrial technical progress with Hicksian neutral technological changes in the two industries. The community indifference curves are assumed to be the same in the two industries, so it is easy to demonstrate that (1) if the income elasticity of demand for manufactured goods is less than unity, country B 's relative price of manufactured

⁸ One must be certain that commodities are consumed in positive amounts, otherwise Gorman's criterion would be wrong. See Samuelson [18, p. 5, footnote 2].

FIGURE 4

goods is less than country A 's, (2) if the income elasticity of demand for manufactured goods is greater than unity, country A 's relative price of manufactured goods is less than country B 's, and (3) if the identical community taste patterns are homothetic, both countries are at equilibrium without any trade.

Let us return to the Heckscher-Ohlin case, where the factor endowment ratios differ between the two countries. In Figure 4, the point a is assumed to be country A 's initial closed economy equilibrium point. The curve $B'B^1$ is the initial transformation curve of country B . The slopes of lines t_a and t_b are the two countries' closed economy commodity price ratios, with the output ratio of the slope of the ray λ' assuming the same production at the point a in the two countries. The rays λ' and ρ' are respectively country A 's and country B 's economic expansion paths with the commodity price ratio of the slope of line t_a when Hicksian neutral technical progress occurs to the same degree in the two industries. From Figure 4 some simple but important propositions become clear.

First, if the Engel curve rises at a slope less than the ray ρ' , such as a QT'' , it must intersect country B 's production expansion path ρ' at some point Q . Country B 's new transformation curve may (i) cut the ray ρ' below the point Q , (ii) cut it at the point Q , or (iii) cut it above the point Q , depending upon the scale of country B 's economy caused by technical progress. In case (i), the closed economy product price ratio, P_F/P_M , is lower in country A than in country B so that the Heck-

sch-Ohlin theory must hold. In case (ii) they are equivalent so that there is no trade between the two countries even though the factor endowment ratios and the technology differ between them. In case (iii), the capital abundant country, *A*, will export the labor intensive commodity, *M*, in exchange for the import of the labor intensive commodity, *F*. Clearly, the Leontief paradox occurs under these assumptions if, and only if, the scale of country *B*'s economy caused by technical progress is large enough compared with country *A*'s, so that the corresponding transformation curve cuts the ray ρ' above the point *Q*. When the Engel curve rises at a slope greater than the ρ' but less than the ray λ' so that there is no intersection of the Engel curve and country *B*'s production expansion path, then the Heckscher-Ohlin theory must always hold.

Secondly, if the Engel curve rises at a slope greater than the ray λ' such as *RaT'*, it must intersect country *B*'s production expansion ray, ρ' at some point *R*. Country *B*'s transformation curve may (i) cut the ray ρ' below the point *R*, (ii) cut it at the point *R*, or (iii) cut it above the point *R*. In case (i), the closed economy price ratio, P_F/P_M , is higher in country *A* than in country *B*, so that the Leontief paradox must hold. That is, under these assumptions the Leontief paradox holds if and only if the scale of country *B*'s economy is small enough compared with country *A*'s, so that the corresponding transformation curve cuts the ray ρ' below the point *R*. In case (ii) there is no trade between the two countries. Clearly, the Heckscher-Ohlin theory must hold in case (iii).

Thirdly, if the demand expansion curve is a straight line, such as *OaT* (that is, the demand pattern is homothetic), it never intersects the ray ρ' , so that the Heckscher-Ohlin theory must hold.⁹

The closed economy factor price ratios in the two countries are obtained from the Stolper-Samuelson theorem [19] when the same degree of Hicksian technical progress occurs in the two industries in one country.¹⁰ In all cases in which the Heckscher-Ohlin theory of the trade pattern holds, the relationships between commodity and factor price ratios in the two countries are represented by:

$$\left(\frac{P_F}{P_M}\right)_A < \left(\frac{P_F}{P_M}\right)_B \quad \text{implies} \quad \left(\frac{r}{w}\right)_A < \left(\frac{r}{w}\right)_B.$$

⁹ The third case was pointed out by Jones [10, p. 4, footnote 1].

¹⁰ Notice that I modify here the meaning of the Stolper-Samuelson theorem. The original Stolper-Samuelson theorem asserts that, by the imposition of an import duty, the real reward of whichever factor is employed intensively in the import-competing industry rises, and the real reward of the other factor contracts. But I use the theorem in terms of the relative reward to each factor.

On the other hand, in all the cases in which the Leontief paradox holds, these relations will be given by:

$$\left(\frac{P_F}{P_M}\right)_A > \left(\frac{P_F}{P_M}\right)_B \text{ implies } \left(\frac{r}{w}\right)_A > \left(\frac{r}{w}\right)_B.$$

The reverse relation is also true in both cases. Each country exports always a commodity which is produced by using intensively a cheaper factor compared with the other country. In other words, if factor abundance is defined by the pre-trade ratios of factor prices between

FIGURE 5

the two countries as Heckscher did, the Heckscher-Ohlin theory always holds.

Now I abandon the assumption of the same extent of Hicksian neutral technical progress in both industries in country *B*, assuming still no technical change in country *A*. The crucial modification of this model is that country *B*'s production expansion path, ρ' , becomes a curve instead of a straight line. In Figure 5 the curve OGR_2 (or the curve ρ') shows country *B*'s production expansion path which rises at an increasing rate. The shape of country *B*'s production expansion curve may be determined as follows: for instance, when the same degree of Hicksian neutral and capital-saving technical progress occurs respectively in the *F*- and the *M*-industry, the transformation curve will expand such that the output ratio, O_F/O_M , rises at a constant commodity price ratio. If technical progress is continuous and Hicksian

FIGURE 6

capital-saving technical progress in the M industry is such that the unit M isoquant curve shifts to a point above the point j of Figure 3, the production expansion curve ρ' is rising at an increasing rate and does not bend back. If the unit M isoquant curve shifts to a point below j of Figure 3, it bends back like line ρ'' . On the other hand, the dotted lines R_1aT' and aQT'' show respectively inelastic and elastic income demand expansion curves for manufactured goods. Of course, the line OaT shows the homothetic demand taste pattern.

When country B 's production expansion curve rises at an increasing rate, it may cut country A 's production expansion line, the ray λ' , which would be caused by neutral increment of the two factors, say, at the point G . In this case even if the community indifference curves are homothetic (and the demand expansion curve is represented by the ray OaT), the trade pattern changes after country B 's transformation curve cuts the ray at the point G , and the Leontief paradox occurs. But when the income elasticity of demand for manufactured goods is less than unity, such as shown by the line R_1aT' , it may cut the production expansion curve more than once, say, at R_1 and R_2 . In this case the meaning of the point G differs from before. The pattern of trade does not change on both sides of the point G , and the Heckscher-Ohlin theory of the trade pattern holds if, and only if, country B 's transformation curve cuts the curve ρ' at some point inside of the range R_1 and R_2 . On the other hand, the Leontief paradox occurs if, and only if, country B 's transformation curve cuts curve ρ' at some point below R_1 , or above R_2 . In this example, the pattern of trade between the two

FIGURE 7

countries changes three times, and when country *B*'s transformation curve cuts the curve ρ' at R_1 or R_2 , there is no trade. This is true even if the production expansion curve bends back, such as curve ρ'' . If the income elasticity of demand for manufactured goods is greater than unity, such as shown by the line aQT'' , it must intersect the production expansion curve ρ' (or ρ''), say, at the point Q . The point Q is an equilibrium point with no trade between the two countries. The Heckscher-Ohlin theory holds if, and only if, country *B*'s transformation curve cuts the curve ρ' (or ρ'') at some point below Q , while the Leontief paradox holds if, and only if, country *B*'s transformation curve cuts the curve ρ' (or ρ'') at some point above Q .

Of course, these are not all the possible cases. Many other configurations are a priori possible. For example, Figure 6 shows a case in which the demand elasticity for manufactured goods is greater than unity, which is shown by curve aT'' , and country *B*'s production expansion curve is represented by ρ' or ρ'' . There is no intersection between the demand and supply expansion curves so that the trade pattern does not change in the whole area. The Heckscher-Ohlin theory always holds in this situation in spite of different production functions in the two countries. On the other hand, in Figure 7 country *B*'s production expansion curve, ρ' , fluctuates so that it intersects with the demand expansion line, aT'' , several times, that is, at Q_1 , Q_2 , and Q_3 . In this case, the trade pattern changes alternately at those points between the two countries. The Heckscher-Ohlin theory holds at the ranges OQ_1 and Q_2Q_3 ,

while the Leontief paradox occurs between Q_1 and Q_2 , and also above the point Q_3 .

We have demonstrated that the Leontief paradox may occur if we assume identical taste patterns in the two countries. We have obtained also sufficient conditions for the Heckscher-Ohlin theory of the nature of trade pattern when we abandon the assumption of the same production functions in the two countries. Finally, we can easily relax the assumption of identical taste patterns in the two countries. When country B 's taste pattern differs from country A 's, country B 's Engel curve which represents the same commodity price ratio as country A 's closed economy commodity price ratio does not pass through the point a which is assumed to be located on the ray λ' (in Figures 4 to 7). However, notice that the intersection points between country B 's production expansion curve and its Engel curve mentioned above are crucial in our discussion. Whether the Engel curve of country B passes through country A 's closed economy equilibrium point a or not is not necessarily important to consider changes in the trade pattern between the two countries if no technological change occurs in country A . Therefore, all the conclusions do not essentially change if the two countries have different taste patterns.

A New Approach to International Liquidity*

Almost a quarter century ago, Professor Abba Lerner advocated a revolutionary new doctrine he named functional finance. The gist of it was that public spending and taxation should be governed exclusively by the goals of full employment and price stability, without regard to whether the budget was balanced. At the time, this doctrine looked like Lerner at his wildest—today it is fiscal orthodoxy not only in the classroom but in many treasuries and ministries of finance as well.

The idea can be extended into the international sphere. There is a lively discussion going on today of whether or not the supply of international liquidity is adequate; and if not, what would constitute an adequate level. There is much disagreement and little hope of its ever being resolved. All parties to the argument, however, seem to agree on one thing: if the supply of liquidity were to be brought to what is considered an adequate level, all would wish to keep it stable at that level, or, at the most, increase it at an annual rate of three per cent—which is the limit to which respectable economists are willing to stretch the meaning of the word stable, as a concession to the realities of our expanding universe. The reason why the warring factions can agree on this one point is that they all believe in the desirability of balancing, in the long run, the balance of payments. Disagreement on how large a supply of liquidity is adequate is disagreement on how long the long run should be. All economists seem to agree that in the long run, however defined, each country should maintain balance-of-payments equilibrium.

Let me point out first of all that this is a moral doctrine. Our moral conscience tells us that it is not *right* for anyone or any country to get something for nothing—although that, precisely, is what an indefinite balance of payments deficit implies. If the deficit is on the current account of the balance of payments, there is the further connotation that the country lives beyond its means and spends more than it earns, with all the moral disapprobation that this calls forth. It is all right to run a deficit temporarily, in an emergency, and as long as one's reserves allow; but people consider it morally imperative that these reserves be finite and either of the kind that have been earned beforehand or of the kind that must be repaid afterwards. This is the puritan ethic of international trade. What is wrong with it?

What is wrong with it, I think, is that it is ethics rather than economics. Not only is it perfectly good economics occasionally to get something for nothing; it is or should be one of the economist's main preoccupations. It is, indeed, the subject matter of welfare economics. To move from a non-optimal to a Pareto-optimum situation is the art of getting something for nothing. A

* I am indebted to Professors Alvin H. Hansen and Abba P. Lerner for reading the manuscript and making many valuable suggestions.

more pertinent example of this art is public works to relieve unemployment, since these create something, a bridge, or a post office, or tidily raked leaves, whose social cost is nothing or less than nothing, zero or negative.

If we must have a moral doctrine to govern our economic affairs, a much better one would be that no country be required to give up anything without receiving something, an adequate *quid pro quo* in exchange. This is a much less restrictive rule, more acceptable also to the economist; and we shall explore its implications in the following.

The economist has no business to accept unquestioningly and to regard as self-evident dogma the desirability of long-run equilibrium in the balance of payments. There are times and situations when payments balance is, indeed, desirable; but its desirability must be established by economic argument and not treated as a premise. The functional approach to international finance is to forget about payments equilibrium in the long as well as in the short run and to ask instead whether it might not be possible to let each country have the kind of balance of payments that best serves its domestic goals whatever these may be: price stability, fast growth, full employment, or some combination or compromise of these.

The reason, I suspect, why no one so far has bothered to ask this question is that the answer obviously is no. It is obviously not possible to let every country have the balance of payments it needs or wants. The developing countries for example would probably show an insatiable appetite for payments deficits; and even according to the conservative estimate of a banker, Mr. Woods, president of the International Bank for Reconstruction and Development, they could absorb another \$4.5 billion of unrequited imports per annum. But if it is impossible to satisfy every country, might there not be a compromise? There are deficit countries, such as the United States today, that make insufficient use even of their own resources and certainly do not need, and do not want, unrequited resources from abroad. And there are surplus countries that are happy with their surpluses, or at least not unhappy enough to try to eliminate them. Could not a system of international payments be devised to accommodate at least these countries? And if, in the process, some of the developing countries' desire for unrequited imports can also be satisfied, so much the better.

A plan to achieve this will be presented in the following. It will call for the creation by a reformed International Monetary Fund of international paper money, to be made available to developed countries with unemployed resources against their national currencies to be held as security by the IMF, and against real resources to be given as grants to developing countries. But before discussing the detail of this plan, we shall first state its principles and show how they follow from the requirements of functional finance and the new moral doctrine enunciated on the preceding page. It is also worth noting here that the need for some such plan was first stated by a very practical and policy-oriented expert in the field.

Richard Cooper has argued, in contrast to most international-trade theorists, against the devaluation of the dollar (cf. [1]). He was afraid that this

might restore balance-of-payments equilibrium, which, he said, is not what we want—certainly not what we need and ought to want. His argument was that, over the past 15 years, the Western European countries (not to mention Japan) had a very fast rate of growth, unprecedented in Europe; and that this had much to do with their balance-of-payments surpluses, since it was based on export-oriented expansion, which in these countries is more feasible than the expansion of domestic markets, which inevitably increases competition at home. Their payments surpluses in turn were made possible by the persistent payments deficit of the United States, which she did not seem to mind as long as the outside world did not object, and which did not cramp her style of growth either during most of this time. Dollar devaluation might bring to an end this perfectly satisfactory state of affairs by worsening (eliminating the surplus in) the European and Japanese balances of payments. He hoped that we would be able to do better than that—devise some means whereby the Europeans and Japanese could continue their surpluses, we our deficits, and all of us our fast rates of growth.

Let us now try to devise such a system. Deficit countries should certainly not be put under pressure to improve their balances of payments by means of restrictive policies that would lower either the level or the efficiency of employment of their resource capacity, and so inflict a net loss on the world as a whole. Instead, additional international reserves should be created to accommodate these countries, but made available to them only in exchange for goods and services. To exact payment in products for the newly created reserves is to guarantee that they will be claimed, created and used only when, and only to the extent that unemployment or inefficiency exists in the recipient countries or would be created if such reserves were not available. For the social cost of the products paid for the new reserves is zero or less than zero at times of underemployment (or when the alternative to producing them is to create underemployment); whereas it is quite high and likely to be considered prohibitive at times when their production would create or aggravate inflationary pressures. At such times therefore the deficit countries would fear the inflationary pressures of the payment exacted for the new reserves; and, rather than obtain these, they would choose to eliminate the deficit through restrictive fiscal and monetary policies, more appropriate also to the domestic needs of the economy.

The products surrendered in exchange for the newly created reserves would be available to fill part of the development needs of the developing countries; and their composition would have to be suitable for this purpose—a restriction that will be discussed further.

The creation of additional liquidity, and its injection into the system through deficit countries short of reserves, would enable surplus countries to continue their surpluses if they wished to. At the same time, they could also eliminate their surpluses—and simultaneously slow or prevent the creation of additional liquidity—if they found either their surpluses or their reserves excessive. A surplus country can always eliminate its surplus if it wants to (and much more easily than a deficit country can eliminate its deficit), by exchange

revaluation, by temporarily liberalizing imports, by special taxes on foreign tourists or foreign capital, to mention just the more agreeable weapons in the surplus country's armory. By eliminating their surpluses, the surplus countries eliminate also the deficit countries' deficits and thereby prevent their needing, and causing the creation of additional reserves.

Under this plan therefore new reserves could be created only when there are countries with surpluses and deficit countries with unemployed resources. (See, however, p. 1217 below for an exception.) Since the new reserves would be made available primarily to deficit countries and only against products, these countries' domestic and external troubles would be relieved at the same time. The products, obtained against and representing the real counterpart of the newly created reserves, become the unrequited imports of the developing countries, which can always use the right kind of imports from industrial countries with benefit to their economies.

The one seemingly arbitrary element in this scheme is the transfer of products from deficit to developing countries; and the equality of their value to that of the new reserves created (they could just as well be half or twice as great in value).

This latter, however, also has its justification. To provide a country with new reserves and thereby allow it to run a deficit without drawing down either previously earned reserves or subsequently repayable credits amounts to giving that country something for nothing. This can be done without a corresponding loss to other countries only when its acquisition of these new reserves goes hand in hand with the production of output that would not be produced otherwise. The best way to assure this is to require the country that wants additional reserves to surrender in exchange products at least equal in value; and it is a matter of equity to make these available to those most in need.

The deficit country, however, which obtains the new reserves, is enabled to raise its output (or avoid restricting it) by an amount much larger than its new reserves. For its new reserves enable it to make foreign payments in equal amount; and these would equal only the additional imports resulting from the much larger increase in aggregate income and output.

The difference between the additional output and that part of it which is surrendered in exchange for the reserves obtained resembles a Marshallian surplus and is a net gain to the deficit country. Hence the question whether this gain should be allowed to accrue to the deficit country or whether instead it should be transferred, wholly or partly, to the developing countries? In other words, should not \$1 million of newly created reserves be sold at a price higher than \$1 million worth of products? To answer this question it is best to ask first what would happen if the country in need of reserves would not be able to obtain them. It would then have to curtail its foreign payments by a like amount, which it could do by restricting aggregate output by a larger amount: larger in the ratio of the reciprocal of its marginal propensity to import. If this were the only way to curtail foreign payments, additional reserves that made the curtailment unnecessary would be worth more in terms of out-

put than their nominal value. Nevertheless, the recipient country should not be made to pay more than their nominal value for the new reserves, because there are also other and usually cheaper ways of curtailing foreign payments: trade restriction and administrative controls.

When, for lack of reserves, a country curtails its imports through duties, quotas, or administrative controls, the consequent loss is the value of the imports foregone, plus the nuisance value and inefficiency such measures entail. These latter costs, though real, are intangible and difficult to measure; and they may well be offset by the beneficial side effects of import restriction: the stimulus to and protection of domestic production. As a first approximation therefore, the loss created by import restriction may be said to be no more or not much more than the value of the imports foregone. Here, then, is the justification for selling newly created reserves to the country in need neither for more nor for less than the nominal value of the reserves.

Another argument for exacting payment in products for newly created reserves is that it maintains the deficit countries' balance-of-payments discipline for the occasions when this is necessary. It may seem paradoxical to argue for balance-of-payments discipline and adjustment and for reserve creation at the same time. After all, the latter's purpose is to avoid the need for adjustment. Payments adjustment, however, must not and cannot always be avoided; and an ideal system of international payments will both minimize the need for adjustment and encourage and facilitate it when adjustment is required.

This combination of trying both to avoid adjustment when unnecessary and to encourage it when called for is the Scylla and Charybdis on which past reforms have foundered. It seems very hard to provide reserves or extend credit to a deficit country without weakening its will to make payments adjustment in the future. Conditional credits seemed at one stage the solution to the dilemma; but they too proved a broken reed. Yet, this will must be preserved in a world where payments adjustment is often necessary, always painful, and where the pain can only be mitigated by dividing the burden of adjustment between deficit and surplus countries.

It is true that the deficit countries have for many years carried the main burden of adjustment, which makes one wonder if concern to preserve their will to adjust is not misplaced or exaggerated. But the reason why they did most of the adjusting in the past was the world's deflationary bias, with more unemployment in the world than inflationary pressure. If new reserves are created as here proposed, they will not only relieve many deficits but eliminate much of the deflationary bias as well. In fact, my proposal may be regarded as an extension of Keynesian policy into the international sphere. While Keynes wanted to increase the supply of national moneys in order to lower interest rates and so stimulate investment and employment, I am proposing to increase the supply of international reserves in order to eliminate restrictive national policies when these lead, or threaten to lead to unemployment.

If there were no deflationary bias in the world, the surplus countries would be under much more pressure to eliminate their surpluses; and for them to bear the main burden of adjustment in an inflationary world would be just as bad as its opposite. This is why the deficit countries must be made to earn

their reserves and pay for them in products. The social cost of these, and hence of the reserves, depends on the state of the economy; economists as well as the general public are likely to consider this cost prohibitive in inflationary times but worth paying and even beneficial in all others.

Accordingly, the scheme as here outlined would enable deficit countries to obtain newly created reserves when there is unemployment but force them to make payments adjustment when inflation threatens. It would also put indirect pressure on countries with payments surpluses and inflationary pressures to take the initiative in eliminating both.

This raises two questions. First, should not also surplus countries with unemployed resources be allowed to obtain additional reserves on the terms here outlined and so enabled to raise employment levels? Second, is it right to make newly created reserves available to countries with deficits and unemployment at times when these are due to an overvalued currency that has priced the country out of world markets?

The answer to the first question is yes. If a surplus country prefers this way of raising employment or considers its reserves so small that it wants to add to them faster than its surplus allows, there can be no objection to its buying more reserves against products if it can do so without harming other countries and even while benefiting some. This case may be quite important, because developed countries will find it easier to maintain employment by extending foreign aid than by stimulating domestic investment whenever they lack the amount and type of labor needed to man the new equipment that additional domestic investment would create (cf. [2]).

The second question is tricky. One might argue that additional reserves should be made available only to countries in temporary payments difficulties; whereas a permanent payments disequilibrium, and especially one due to misalignment of price levels, should be remedied by exchange-rate readjustment. The principle of functional finance, however, may well give a different answer.

An overvalued currency often leads to both underemployment and payments difficulties; but the country may nevertheless be reluctant to devalue its currency, for fear not only of losing face but also of worsening its terms of trade. Here is a real cost of exchange-rate readjustment, which must be weighed against the cost of producing the goods that would buy the new reserves needed if exchange rates were kept unchanged. This, we argued earlier, involves no social cost at a time of underemployment—at least not in the short run. In the long run, other ways of raising the level of employment must also be considered; and, weighed against such alternatives, the opportunity cost of buying reserves with development aid is quite likely to be positive. Whether this cost will be greater or smaller than the cost of worsened terms of trade cannot be determined *a priori*; there might well be situations in which the country would prefer to keep its currency overvalued indefinitely and finance the resulting payments deficit out of newly created reserves paid for by products. There remains the question how the outside world would view such preference and behavior on the part of the deficit country.

Other developed countries would probably accept and even prefer it. For

they usually regard a fellow developed country not so much as a market in which to buy as one in which to sell and as a competitor in third markets. They are quite likely therefore to live happily with its currency overvalued. As to the developing countries, as a group they would gain either way, perhaps more from development aid than from a slight improvement in their terms of trade.

Having presented the bare bones of the plan and its economic justification, there remains to be added its monetary mechanism, the money veil so to speak. There are many different ways, of course, in which such a plan can be implemented; the following is just one example among many, chosen primarily for simplicity of exposition.

Credit instruments (owned reserves) are preferable to credit, which is why the newly created reserves should be instruments of indebtedness, international paper money, issued by the IMF against the security of member countries' currencies. These Fund Obligations could be created only on the initiative of the countries desirous of obtaining them, though preferably subject to approval by the Fund. If a deficit country, such as the United States, wished to obtain, say, \$1 billion additional reserves, her government would have to have the corresponding appropriation in its budget, so as to be able to hand over to the Fund \$1 billion in U.S. currency. This would also have to carry a gold guaranty. Against the security of the U. S. currency, the Fund would issue \$1 billion worth of Fund Obligations, which would ultimately become part of the U.S. external reserve, acceptable and usable as equivalent to gold by all member countries of the Fund. (To assure this, central banks would have to be required to hold Fund Obligations in prescribed minimum proportions to other reserves.) At first, however, the Fund Obligations would be restricted in use and handed over, not to the United States, but to the International Development Association. The IDA would use them to finance investment projects of developing countries approved by the IBRD's regular screening machinery as technically feasible and economically sound; but giving priority to projects least likely to generate hard-currency earnings and therefore least suitable for financing by loans.

For the \$1 billion would be used by IDA as grants-in-aid, not as loans. They would not be repayable but could be spent only in the originating country (i.e., the country against whose currency they were issued). In other words, they would be "tied gifts," although without restriction as to the commodities on which they could be spent within the country specified.

Once the developing countries spent the \$1 billion Fund Obligations in the originating country (the United States), they would become unrestricted reserves, as good as gold, spendable and acceptable in all member countries. The delay with which the originating country would, under this arrangement, obtain the addition to her external reserves could be eliminated by the Fund's extending to her a line of credit repayable out of the new Fund Obligations as these are spent in, and so reach, the originating country.

This, in a nutshell, is the monetary side of functional international finance. The link it establishes between the creation of international reserves and the

granting of development aid, though often criticized, is a very natural one, with plenty of precedents on the national level. Money in the modern world, whether central-bank money or commercial-bank deposits, has always been *earned* by the people holding it, and paid for in terms of resources that were then made available to business and government to help national economic development. In an expanding world, the demand for international reserves is also expanding; and it makes good sense to fill this demand only against real resources that can contribute to development. At the same time, the newly created Fund Obligations would be backed in this plan by the gold-guaranteed currencies of the developed countries—an essential condition for establishing confidence in an international paper money.

This advantage, however, comes at a price. For one thing, only developed countries would be able to buy newly created reserves from the Fund; for another, they could only buy these reserves through the cumbersome machinery of budgetary appropriation subject to parliamentary or congressional approval. Both restrictions have their justification. The only excuse for creating new reserves is the economic possibility of creating something out of nothing; and this is only possible when unemployed and re-employable resources are present. There is no point, however, in creating additional products that nobody wants, and no justification for creating new reserves against payment in such products. This is why I propose to let the Fund create new reserves only against the currencies of countries that can pay for these reserves in products that developing countries want and need.

As to reliance on the budgetary process when a deficit country wants to augment its reserves, this is a way to remind the public that there is no easy way out of payments difficulties. Imports and foreign investments alike must be paid for by exports; although there are times when these are easily spared and do not reduce domestic availabilities. Both these truths need to be stressed; and the budgetary process is the most likely to accomplish that. This is why it seems the best machinery for an orderly expansion of the world supply of international reserves and the best safeguard against inflation.

This brings us to another apparent shortcoming of the plan: the tied nature of the aid, which is the counterpart of reserve creation. A tied gift, however, is very different from a tied loan and free from the latter's shortcomings. The objection to a tied loan is that it can be expensive. Interest and repayment that seem reasonable in money terms may prove exorbitant and usurious when the debtor is forced to buy at the creditor's high prices. By contrast, a gift, even a tied gift is unrequited generosity; and there is truth in the saying that one must not look a gift-horse in the mouth.

The purpose of tying grants-in-aid is to confine their expansionary influence to the deficit country that has decided that its economy can afford the additional exports and absorb the expansionary effects they entail. The tying of aid therefore is a safeguard against the inflationary influence of reserve creation.

It is true that money is fungible and tying seldom 100 per cent effective. In this case, however, there are two guaranties of reasonable effectiveness. One is that such grants-in-aid would finance specific development projects and could

be spent only on goods and services needed for these. The other is the developing countries' desperate need for development aid, which assures that such grants-in-aid would become additional expenditure and not the alternative financing of goods imported in any case.

It may be noted in closing that reserve creation as here outlined is designed and suitable for the secular expansion of international reserves in keeping with the needs of an expanding world economy. It would be too slow and cumbersome to deal with payments problems created by crises of confidence, which are best countered by bilateral (or multilateral) credit or swap arrangements

Moral Suasion as an Instrument of Economic Policy

Christopher Robin goes
Hoppity, hoppity
Hoppity, hoppity, hop
Whenever I tell him politely to stop it, he
Says he can't possibly stop

—A. A. MILNE

In the fourth century, Emperor Julian the Apostate exhorted the merchant of Antioch to hold down wheat prices—with a spectacular lack of success [2, p 801]. Long lurking in the box of little-used policy tools, moral suasion appears to be undergoing a modern-day resurrection. In recent years one can observe both a marked increase in governmental (and particularly, presidential) suasion as a policy instrument as well as (at least) a superficial increase in its effectiveness. Recent examples of moral suasion are legion: the Kennedy-U.S. Steel and Johnson-aluminum, -copper and -steel industry confrontations; implementation of wage-price guideposts; top level mediation in labor-management disputes; "voluntary" curbs on foreign investment and travel; "jaw bone" exhortations to business to pass the "savings" arising from excise tax cuts on to consumers; and many, many more.

There is little evidence that moral suasion is being used wholly as a substitute for other instruments of economic policy. The increasing number and complexity of government policy objectives has led to increased use of all policy instruments, monetary, fiscal, etc. As Tinbergen has demonstrated, the instruments of policy must be at least as numerous as the number of policy objectives [5, pp. 1-4], and one way of viewing moral suasion is that govern-

ment has grasped it as an additional instrument to meet its increasingly numerous economic objectives. But there are many objections that can be raised concerning the use of moral suasion as a major policy instrument. Moral suasion is inequitable in that it rewards noncompliance; it constitutes extra-legal coercion by government without judicial review; it is in violation of the "rule of law"; where promises, implicit or explicit, are involved, it entails the danger of an overly familiar relationship between regulator and regulatee; its *ad hoc* character adds an additional and unnecessary element of uncertainty to business decisions; and it may frequently be used in lieu of (i.e., as an excuse for not implementing) more effective legislation.

Indicting as this list may be, it does not prove that moral suasion is inferior to other types of policy instruments. All policies have opportunity costs both in terms of their administrative and enforcement costs as well as their allocative effects on the economy. Whether moral suasion is inferior to other instruments or whether a partially effective moral suasion policy is even superior to a policy of doing nothing at all depends upon the relative costs and effectiveness of alternative policies and the value system within which the relative costs and benefits are weighed.

The purpose of this paper is not to examine the ethical or political or even all the economic implications of this increasingly popular policy instrument. Rather, the objective is to point out the necessary conditions for moral suasion to be an effective policy instrument. It will be argued that (1) the necessary conditions for a moral suasion policy to be successful in achieving any desired goal constitute a special, not a general, case in the economy; and (2) the presence of these necessary conditions may well be promoted by existing trends in the economy so that over time we may expect to see a continued increase in both the incidence and effectiveness of policies implemented through moral suasion.

Since the concern of this paper is with moral suasion only in the economic sphere, moral suasion will be defined here as the attempt to coerce private economic activity via governmental exhortation in directions not already defined or dictated by *existing* statute law. It is, in a sense, the extreme case of "rule of men" as opposed to "rule of law."

The meaning of the appellation *moral* in the term moral suasion is not at all clear. (Whoever heard of an economic policy of immoral suasion?) Possibly the purpose of the appellation is to distinguish *pure* moral suasion, an appeal for altruistic behavior, from other types of persuasion which are backed by threats of punishment and/or promises of reward. However, as a practical matter, pure moral suasion rarely has been used as serious economic policy.¹ Also, it is not at all clear how altruism enters utility functions, if in fact it ever does. Fortunately, the question of the degree to which altruistic considerations influence economic behavior is not crucial, for the basic difference between moral suasion and direct suasion via the "rule of law" is not the threat

¹ An exception might be appeals to patriotism in times of national emergency. The "Buy War Bonds" campaign of World War II, for example, was rather successful. To be sure, there were other incentives provided via rationing policies and in the interest paid on the bonds. But the interest rate was not *raised*.

of punishment or promise of reward. Rather, it is that punishment does not *automatically and uniformly* fall upon the (apprehended) noncomplier to moral suasion as it does upon the violator of statute law. For where moral suasion is buttressed by implicit or explicit threats, even if the policy fails, the threats might not be carried out, and if only a minority does not comply the moral suasion policy is likely to be deemed a success, and no follow-up action is required or taken. (The immorality of moral suasion is quite clear here. It rewards the noncomplier and punishes the socially cooperative and conscientious.) Although, in some unworldly sense, moral suasion might carry with it no threat of punishment or promise of reward, in a real sense, if the policy constitutes anything more than innocuous pontification to the economy as a whole, it carries at a minimum the implied threat of future legislation. In addition, the threat of fully utilizing existing regulatory powers; the danger of incurring government displeasure and inspiring legal prosecution on completely unrelated grounds; the possibility of being pointed out for public ridicule and abandonment or the promise of reciprocating favors may also play a role in instances of moral suasion, both successful and unsuccessful.

Assuming intelligent government, moral suasion is exerted in the economic sphere only in instances and directions which promote the national economic welfare (as viewed from the government's objective function). Assuming rational, profit-oriented economic units, existing private economic activity is already maximizing each unit's own economic welfare. The sphere for moral suasion, or any other economic policy, is where individual profit-seeking activity does not maximize the national welfare, i.e., where the particular and the social interests diverge. Thus, moral suasion must encourage private economic units to undertake actions which are unprofitable and which they would not undertake otherwise.

It is worth noting that the strongest protagonists on the one hand and the strongest opponents of moral suasion policies on the other, both in the abstract and on particular issues, use the lack of one or the other of the above assumptions as the main foundation of their position. Proponents of moral suasion argue that it is to the long-run benefit of private units to comply with the government persuasion ("What's good for the United States is good for General Motors . . .") implying that private units are presently acting irrationally and not maximizing (long-run) profits. On the other hand, opponents of moral suasion argue that government's position is misguided; that in fact compliance with government wishes would *not* increase national welfare ("... and vice versa"). It is not in the national interest, they argue, to hold down aluminum or steel prices to "subsistence levels" or to take firemen off trains, etc. Neither side addresses itself to the only real dilemma: the situation where both government and private units are acting rationally in the light of their own objective functions. In what follows, intelligence and rationality are assumed on the part of all parties.² Eschewing from this discussion the cases

² To discuss moral suasion in any other context is in reality to discuss education, itself. Although not of direct concern here, the educational aspect should not be ignored. Education may be good even if it masquerades under the title of moral suasion, and educational benefits are frequently used to justify—or rationalize—moral suasion policies. This is the

where government policy is in fact not promoting the national economic welfare or where private activity is in fact not maximizing each individual unit's welfare in no way defines away the problems involved in implementing economic policy through moral suasion. On the contrary, it only disjoins those dilemmas which can be potentially resolved through intelligent and rational discourse from the dilemmas in which private and public objective functions, rationally and intelligently arrived at, are still in conflict.

Within this frame of reference, it can be somewhat tautologically asserted that moral suasion can be an effective economic policy whenever the expected cost of noncompliance is made to exceed the cost of compliance. However, there are conditions which must exist in order to so design a moral suasion policy, and these conditions severely limit the size of the set of potentially effective moral suasion policies. There are two necessary conditions for the success of a moral suasion policy. The first is a long-run condition only; the second is both short- and long-run.

1. *The public must support the government's position.* Strong involvement with the public interest increases both the scope for altruism as well as the probability that threats will be carried out. A glare of publicity can increase the power of persuasion *ex ante* (by increasing the expected cost of noncompliance) and the degree of censure on non-compliers *ex post*. However, this is only a necessary condition for an effective moral suasion policy in the long run, for fear of public displeasure is only one of the possible threats or promises with which government might back a moral suasion policy. In the short run it may be possible to establish sufficient expectations of other costs for noncompliers. But in the long run, given that economic policies are made in a democratic framework, the public must support these policies politically. This is particularly true when moral suasion is used recurrently against the same group.

2. *The populations to be persuaded must be small.* Moral suasion appears to be completely ineffective when exerted upon a large population. Fewness makes noncompliers readily identifiable and places responsibility for the success of the policy specifically and directly upon a small number of individual units so that credit for success, or blame for failure, can be levied. The analogy with central banking practices in the United States and England is an obvious one. Moral suasion is a cornerstone of English, but not U.S. monetary policy, presumably because in England there are only five major banks which need to be persuaded. A noncooperator can be immediately identified and held up for censure. On the other hand, the Federal Reserve uses a superstructure of legalistic controls to pursue the same ends. There are too many commercial banks to identify culprits.

case with the wage-price guideposts, for example. The function of mediators in labor-management disputes is usually explained on educational grounds as well. Similarly the reverse case, in which government is in some sense misguided, is not an irrelevant one. The government is not tutelar nor infallible and its objective function is not necessarily equivalent to the *national welfare*. It is not necessarily equivalent to anything even remotely approaching it. Rather it is more equivalent to some such concept as the *majority opinion* or the *compromise of the majority power*.

Furthermore, with only five banks, not only are the effects of the actions of any one bank readily visible, but any one bank itself may determine the success or failure of the policy. When there are many thousands of units, thousands may refuse to cooperate and the policy may still be deemed a success, and no retaliation is levied on noncooperators. In sum, as the size of the population to be persuaded *decreases*, the probability that punishments will actually be levied on noncompliers *increases*.

The necessity for a small population to be persuaded is particularly apparent in cases of divergent firm and industry interests, for here the opportunity cost of compliance for any one unit increases as the number of units which comply increases. In essence, the greater the number of compliers, the greater the cost of compliance. This is the composition problem familiar in agriculture where it may be to the interest of all farmers to cut production in order to raise price, but not to the interest of any one farmer to do so. If the short-run average cost curve is flat, then a small number of noncompliers can produce the market share relinquished by a large number of compliers. Contrariwise, if the average cost curve is U-shaped, then cutting output can raise costs to compliers. In either case, compliers quite likely lose absolutely and always lose relatively to noncompliers. For moral suasion to be effective here it must impose a high probability of punishment on noncompliers and for this, as I have argued, fewness is necessary.

Fewness also implies a closer and more direct correspondence between individual action and public interest. If the cost of compliance is small and the fewness condition is met, moral suasion backed by altruism alone might be effective.

The failures of modern day programs for business to voluntarily restrict investment and banks to curtail credit abroad; for vacationers to restrict their tourism abroad; or for business to pass on to consumers all "savings" from excise tax cuts can be credited directly to the fact that the population which the government was attempting to persuade was too large.⁸ (This was Emperor Julian's problem also.) On the other hand, government's relative success in imposing the wage-price guideposts in specific oligopolistic industries and in high-level mediation of labor-management disputes can be credited to the fact that the fewness condition was met.

The fewness condition imposes a severe limitation on the applicability of moral suasion as an instrument of policy, and it cannot be artificially satisfied

⁸ One possible exception to the fewness rule, although again associated with a time of national emergency, was the implementation of the Defense Production Act during the Korean War [3, pp. 196-97] [3], [6], [7]. One aspect of this act, administered by the Federal Reserve, was for voluntary restraint by lending institutions in extending credit for nonwar and nonessential purposes. It is generally considered to have been a successful policy reaching a pinnacle of success when investment banks refused to handle state bonds issued to finance a veterans' bonus. The reasons for the relative success of this policy are probably: (1) patriotism in time of war may be a temporary exception to the fewness rule; (2) there was an attempt to achieve fewness by administering this program via regional Credit Restraint Committees consisting of representatives of local lending institutions; and (3) given the existing demand for credit at this time, the cost of compliance may have been so small that a negligible cost imposed on noncompliance could make the policy effective.

by arbitrarily delineating a small population to be persuaded. Generally, the population to be persuaded must be as large as the population which policy-makers desire to affect. One cannot, for example, successfully exert persuasion on some of the firms in a given industry to cut prices. The exception of course is where persuasion is exerted on only the price leader of an oligopolistic industry; and such industries meet the fewness condition by definition.

Fewness also implies the existence of sufficient market power to affect the public interest. Given that some level of restraint is required on economic activity, insofar as competition declines as concentration increases, substitute restraints must come from either increased governmental controls or from moral suasion. This offers a possible reason why we have observed and may continue to observe increasing use of moral suasion as an economic policy. Greater concentration in the economy increases both the effectiveness of moral suasion as well as the need for restraining policies.⁴ In addition to concentration generally, the continuing growth of firms into national vis-à-vis regional markets in response to transportation and other technological improvements encourages the use and promotes the effectiveness of moral suasion. Concentration in the national market meets the fewness condition far better than does an equal degree of concentration in regional markets. In the latter, identification with the *national* interest is not close; a moral suasion policy is more difficult to administer; the probability that implied punishments will actually be levied is much less; and insofar as intermarket competition exists on at least the regional boundaries, the need for restraining policy is less as well. The geographic organization and regional bargaining practices of many labor unions, for example, might explain why labor is (as many argue) less susceptible to moral suasion than is business whose markets are more likely to be national in scope. Increasing concentration and rise of firms into national markets along with the increasing involvement of government in the economy, a possibly more representative government in a more complex economy, and a strong desire to maintain "free institutions" even where they may conflict with other policy objectives, undoubtedly explains the rise in popularity of policies implemented through moral suasion.

J. T. ROMANS*

⁴ It is well known that the evidence in support of the view that concentration is increasing in the economy is not overwhelming. The state of the art of measuring industrial concentration is such that the results depend upon the particular measure and time interval adopted. In terms of the long run and in terms of expansion and concentration in the national market, however, the evidence supports the view that concentration is increasing [1] [4].

The Supply of Storage Revisited

"... prices quoted at one time in a futures market, for two dates of delivery, stand in a relation which in general *does not* reflect expectations regarding events that may occur between the two delivery dates." So stated Holbrook Working [12, p. 1255] in his fundamental article on the price of storage.

Working illustrated his point in terms of the U.S. wheat market. It is typical during a crop year following a relatively sparse harvest that the May (pre-harvest) wheat futures contract will trade at a premium over the September (post-harvest) future. To Working, the magnitude of this premium was in general *not* a function of either the expected size or the expected timing of the forthcoming harvest: "... the price of May wheat (in April, let us say) is above the price of wheat for September delivery because the *last* crop was small (perhaps the carryover from still earlier crops was small also, contributing to the effect). So far as suppliers are concerned, it is only supplies *already in existence* which have any significant bearing on a current inter-temporal price relation of this sort" [12, pp. 1255-56]. This observation was based at least in part on some of Working's earlier empirical findings [10] [11].

Working's hypothesis is particularly useful because it places in proper perspective the dominating role which stocks play in determining inter-temporal price relationships (i.e. relationships between expected prices for the delivery of a commodity at different points in time). On the other hand, insofar as it reflects the consideration of a special case, the hypothesis is incomplete and in part misleading. An investigation of this point not only clarifies the theory of intertemporal price relationships, but what is of greater interest, it also yields a theory explaining the dynamic behavior of commodity spot prices.

I. The Supply of Storage

The fundamental relationship which gave rise to Working's hypothesis is the "supply of storage" curve, illustrated in Figure 1. For very low current

inventory levels, the spot price of a commodity is at a substantial premium to the forward price as a reflection of the high marginal "convenience yield" which the aggregated processors and merchants gain from holding the small aggregate inventory. The convenience for manufacturers comes in the form of avoiding plant closings, and maintaining at least a modicum of cost coverage against finished product price quotations. For merchants, stocks are necessary for a continuing flow of trading. As the aggregate inventory increases, the marginal convenience yield declines to zero, and the expected forward price exceeds the spot price by carrying costs (warehousing fees, insurance, shrinkage, etc.). Finally, given very large aggregate inventory levels commodity holders can be induced to carry additional stocks only by the expectation of a return, or risk premium, for so doing.¹

FIGURE 1. SUPPLY OF STORAGE CURVE

The supply of storage curve portrays the expected price change over some finite interval as a function solely of the *current* aggregate inventory level,

$$(1) \quad \frac{P_t^{*h} - P_t}{h} = f_h(I_t)$$

where,

f_h = Supply of storage function for an interval of h time units.²

The interesting point is that equation (1) is questionable on both theoretical and empirical grounds.

First, the hypothesis involves something of a logical inconsistency. Con-

¹ See Working [12] and Brennan [2] for more detailed discussions of the supply of storage curve. The supply of storage function presented and discussed here relates to a market devoid of futures trading. The introduction of futures trading into a commodity market tends to flatten the supply of storage curve somewhat by virtue of the fact that such trading allows additional persons (i.e., futures speculators) to own stocks during times of surplus, and to supply stocks during times of shortage. But the general shape of the curve shown in Figure 1 remains unchanged. For discussions of the role played by futures trading in supply of storage theory, see Cootner [4] [5], Stein [8], and the author's dissertation [9].

² We are assuming here that expected consumption over the horizon interval, h , is constant, since the convenience yield of the inventory is clearly a function of the amount of coverage it provides for expected needs. Relaxing this assumption would complicate but leave essentially unchanged the arguments which follow.

sider equation (1) written for a general time interval in the pattern of price expectations,³ starting at horizon time, h , and having a length, dh :

$$(2) \quad \frac{P_t^{*h+dh} - P_t^{*h}}{dh} = f_{dh}(I_t^{*h})$$

where,

P_t^{*h} = Expected spot price h months in the future;

h = Horizon time of initial expectation;

dh = Interval between expectations;

I_t^{*h} = Inventory level expected h months in the future.

Now if we let dh approach zero, so that the inventory level can be assumed to remain constant over the very short interval, dh , we have,

$$(3) \quad \frac{dP_t^{*h}}{dh} = f(I_t^{*h})$$

where,

f = Incremental supply of storage function.

Then the supply of storage function linking the spot price with the price expected at some non-zero horizon time can be derived as follows:

$$(4) \quad P_t^{*h} = P_t^{*0} + \int_0^h f(I_t^{*h}) dh$$

But since the expected spot price at a zero horizon (P_t^{*0}) is simply the spot price, we have the general supply of storage function for a specific horizon,⁴

$$(5) \quad \frac{P_t^{*h} - P_t}{h} = \frac{1}{h} \int_0^h f(I_t^{*h}) dh$$

That is, *the spread between the spot price and the price expected at some future time is a function of expected inventory behavior over the intervening interval.*

Figure 2 provides an empirical example of the effect of changes in inventory expectations on intertemporal price relationships. The context is the cocoa market, and futures prices are used instead of expected spot prices. During the 1959-60 autumn and winter period, market estimates of the size

³ The rationale for writing equation (1) in this form is that if equation (1) explains the intertemporal price difference between the present and some future time, then with a suitable replacement of variables, it should also explain the intertemporal price difference between two future points in time. This is akin to Muth's "rational expectations" hypothesis: "... expectations, since they are informal predictions of future events, are essentially the same as the predictions of the relevant economic theory" [6, p. 316].

⁴ To my knowledge this formulation is original to Samuelson [7, pp. 217-18], though he did not put it in quite this way.

FIGURE 2. COCOA FUTURES PRICES, NOVEMBER-DECEMBER, 1959

of the African main crops being harvested increased significantly. The result was a decline in the entire futures price structure during the interval from mid-November to mid-December. The crops did not become fully available to the market in time to prevent a relative shortage during December; hence, the existence of inverse carrying charges between the December and March futures, at both of the illustrated dates. But the increase in crop expectations was large enough to cause the market to shift from expecting a continued relative shortage after December to expecting something of a surplus. This shift in expectations is indicated by the shift in spreads between the successive futures beginning with March, from inverse carrying charges in November to positive carrying charges in December.

Equation (1) is a special case of equation (5) in that it relates to those instances which arise, especially in the case of an agricultural commodity with a highly lumped harvest, where the expected future inventory pattern during a large portion of each season can be approximately stated in terms of the current inventory level (e.g., after the harvest the inventory tends continuously to decline until the next harvest). That is, one can write,

$$(6) \quad I_t^{*h} = g(I_t, h)$$

which when substituted in equation (5), yields

$$(7) \quad \frac{P_t^{*h} - P_t}{h} = \frac{1}{h} \int_0^h f[g(I_t, h)] dh$$

which is consistent with equation (1) and Working's conclusion if,

$$(8) \quad f_h(I_t) = \frac{1}{h} \int_0^h f[g(I_t, h)] dh$$

where,

f_h = Supply of storage function for an interval of h time units;

f = Incremental supply of storage function.

II. The Spot Price Function

The supply of storage theory embodied in equations (3) and (5) explains the behavior of intertemporal differences in price expectations in terms of expected inventory behavior. But as was indicated earlier, the supply of storage concept is also useful in explaining dynamic spot price behavior, given certain further assumptions.

Consider the following system of equations describing a general commodity industry:

$$(9) \quad C_t = C^* - b(P_t - P^*)$$

$$(10) \quad H_t = H^* + e_t$$

$$(11) \quad I_t = I_0 + \int_0^t (H_t - C_t) dt$$

$$(12) \quad \frac{dP_t^{*h}}{dh} = a(I_t^{*h} - I^*)$$

where,

$$b > 0; \quad a > 0; \quad C^* = H^*;$$

and,

C = Consumption

P = Spot price

H = Production (harvest)

I = Inventory

P^{*h} = Price expected at horizon interval, h (i.e., at time = $t+h$)

I^{*h} = Inventory level expected at horizon interval, h

P^* = Equilibrium price

C^* = Equilibrium consumption

H^* = Equilibrium production

I^* = Equilibrium inventory

The harvest rate is postulated as varying randomly about a constant (equilibrium) rate. The equilibrium values of price and consumption are so named because, when price is at its equilibrium value, consumption is at its equilibrium value and is equal to equilibrium production. When the expected inventory level is at its equilibrium value in the supply of storage

function—equation (12), which is a linear version of equation (3)—the expected price remains constant.

Now we can solve the above model for the expected future behavior of price and inventory, if we assume that expected consumption is related to expected price by equation (9), that expected production is constant at H^e , and that expected inventory behavior can be derived according to equation (11):⁵

$$(13) \quad C_t^{*h} = C^e - b(P_t^{*h} - P^e)$$

$$(14) \quad H_t^{*h} = H^e = C^e$$

$$(15) \quad I_t^{*h} = I_t + \int_t^h (H_t^{*h} - C_t^{*h}) dh$$

Taking the second derivative of (15) with respect to h , we have,

$$(16) \quad \frac{d^2}{dh^2} I_t^{*h} = \frac{d}{dh} H_t^{*h} - \frac{d}{dh} C_t^{*h}$$

or, using equations (12), (13), and (14),

$$(17) \quad \frac{d^2}{dh^2} I_t^{*h} - abI_t^{*h} = -abI^e$$

which, given the inventory at the beginning of the expectation period (i.e., I_t , the current inventory), and the restriction that both a and b must be positive, has the stable solution,⁶

$$(18) \quad I_t^{*h} = I^e + (I_t - I^e)e^{-\sqrt{ab}h}$$

so that, as the horizon becomes large, the expected inventory approaches the equilibrium level. Substituting (18) into (12), and integrating with respect to h , yields,⁷

$$(19) \quad P_t^{*h} = P_t^{*0} + \int_0^h a(I_t - I^e)e^{-\sqrt{ab}h} dh$$

⁵ These assumptions are a direct application of Muth's rational expectations hypothesis, in that the expected future values of the variables in the system are interrelated in the same manner as are the actual values. The random element in production is not predictable, and is assumed constant at its (zero) expected value.

⁶ This is only one of an infinite set of possible solutions to equation (17), given the initial inventory level and no other boundary conditions. This particular solution is based on the behavioral assumption that for very large values of h , the inventory will be assumed to be approximately at its equilibrium level. This is the only solution to equation (17) which does not eventually lead to an exponential explosion in the values of the system's variables, which explosion would involve the implausible combination of price and inventory values simultaneously either both above or both below their respective equilibrium levels on a continuous basis.

⁷ Note that equations (18) and (19) constitute a special case of equations (6) and (7).

or,

$$(20) \quad P_t^{*h} = P_t + \frac{a}{b} (I_t - I^*) (1 - e^{-\sqrt{ab}h}).$$

Now the expectation that the inventory will approach its equilibrium level implies that the price is expected to approach some constant level (see equation [12]), and this must be the equilibrium price level since a constant inventory implies a consumption rate equal to the production rate.⁸ Therefore, allowing the horizon time, h , to become large in equation (20), we have,

$$(21) \quad P^e = P_t + \frac{a}{b} (I_t - I^*)$$

or,

$$(22) \quad P_t = P^e - \frac{a}{b} (I_t - I^*)$$

Within the confines of our special case, this result is of great importance. It says that if: (a) in arriving at their expectations people assume that expected behavior is generated by the same equation system that they feel generates actual behavior (i.e., Muth's rational expectations hypothesis holds), and (b) people behave as if their expectations were certain to come true (i.e., their expectations constitute certainty equivalents), then the current price is a function of the current inventory level alone.⁹

Now consider a generalized version of equations (9) through (12), such that both consumption and production are functions of *lagged* price (as is likely to be the case in general), and the supply of storage curve is curvilinear. A general solution of the resulting equation system is no longer attainable (the differential equation corresponding to (17) becomes high order and non-linear). Nevertheless, given certain behavioral assumptions about the generation of expectations in actual commodity markets, we can rescue some of the potential generality of equation (22).

First, it is common in commodity markets for there to exist published

⁸ Samuelson [6, pp. 211-19] shows that this stability characteristic of a model having the general form of equations (18) through (21) holds as long as the demand curve has a negative slope,

$$dC_t/dP_t < 0 \quad \text{for all } P_t$$

and the supply of storage curve has a positive slope,

$$\frac{d}{dI_t^{*h}} \left[\frac{dP_t^{*h}}{dh} \right] > 0 \quad \text{for all } I_t^{*h}$$

and the behavioral assumption footnoted above is made.

⁹ Using similar assumptions, Beckmann [1, p. 10] reaches a similar conclusion. While the model presented above is continuous and linear, Beckmann's model is discrete and non-linear (he in effect uses a kinked supply of storage function), but the results are analogous.

forecasts of production and consumption (and therefore inventory) behavior over some finite horizon period, usually one year or less. These expectations can be substituted into equation (5) to yield a relationship between the spot price and the price expected at the end of the finite horizon interval, h_1 ,

$$(23) \quad P_t = P_t^{*h_1} - \int_0^{h_1} f(I_t^{*h}) dh$$

where,

- P = Spot price;
- P^{*h_1} = Spot price expected at horizon time, h_1 ;
- I^{*h} = Inventory expected at horizon time, h .

Now if the expected behavior of the inventory over the horizon interval can be approximately stated in terms of its beginning value (I) and its ending value (I^{*h_1}) in such a way that equation (23) is integrable, then we have the approximation,

$$(24) \quad P_t = P_t^{*h_1} - F^{h_1}(I_t, I^{*h_1})$$

where,

$$(25) \quad F^{h_1}(I_t, I^{*h_1}) = \int_0^{h_1} f(I_t^{*h}) dh$$

Second, if we can further assume that after the end of the horizon interval, h_1 , both the price and inventory are expected to approach gradually their expected equilibrium values,¹⁰ then again using equation (5) we can write,

$$(26) \quad P_t^{*h_1} = P^e - \int_{h_1}^{\infty} f(I_t^{*h}) dh$$

And if the expected behavior of the inventory over the period after h_1 can be approximately stated in terms of its expected values at $h_1(I^{*h_1})$ and to infinity (I^e , its expected equilibrium value) in such a way that (26) is integrable then we have,

$$(27) \quad P_t^{*h_1} = P_t^e - F^{\infty}(I_t^{*h_1}, I^e)$$

¹⁰ If the characteristic dynamic behavior of the actual commodity system is not purely damped, this assumption may violate Muth's rational expectations hypothesis. For example the lag structure of the system may be such as to generate long-run fairly damped (i.e., irregular) oscillations around an equilibrium state in response to exogenous random disturbances. But if the system structure is complex enough to generate oscillations, Muth's hypothesis that market expectations are based on an awareness of that structure (at least to the same degree that economic theorists are aware of the structure) may be unreasonable. As long as the oscillations are fairly damped around relatively constant equilibrium values, it may be more reasonable to assume that market participants at any point in time expect the system variables to approach equilibrium in a purely damped (non-oscillatory) fashion.

where,

$$(28) \quad F^{\infty}(I_t^{*h_1}, I_t^e) = \int_{h_1}^{\infty} f(I_t^{*h}) dh$$

Combining (24) and (27) yields,

$$(29) \quad P_t = P_t^e - F^{h_1}(I_t, I_t^{*h_1}) - F^{\infty}(I_t^{*h_1}, I_t^e)$$

Again within the limits set by the underlying assumptions, equation (29) is potentially of fundamental importance. It indicates that the spot price can be approximately stated as a function of the current inventory, the market's inventory forecast for some finite horizon, and the expected long-run equilibrium levels of price and inventory.

Hidden Unemployment 1953-62—A Quantitative Analysis by Age and Sex: Comment

In a recent article in this journal [1] Thomas Dernburg and Kenneth Strand presented a labor market model which was used to estimate hypothetical labor force participation ratios and unemployment rates by age and sex for the years 1954 and 1962 under assumed conditions of 4 per cent total unemployment in both years. Their estimates of the distribution of unemployment at 4 per cent total unemployment showed a heavier concentration among young and old males and all female groups (marginal workers) in 1962 than in 1954, supporting one conclusion that "The economy has not yet been able to adjust to the sizable shifts in the structure of the labor force that have taken place over the decade." This is an important finding. I submit, however, that it does not necessarily follow from the model which the authors presented.

Before elaborating, it will be useful to review first certain aspects of the authors' basic equations. Their estimates of unemployment in the model derive from two separate sets of equations on employment and labor force participation by age and sex. The underlying data used in estimating the equations were divided into 14 age-sex groups using monthly observations for the period 1953-62 inclusive. The labor force and employment equations took the following forms, respectively:

$$(1) (Li/P)_t = a + a_1(E/P)_t + a_2(X/P)_{t+2} + a_3(1/P)_t + a_4(Pi/P)_t + r,$$

and

$$(2) (Ei/P)_t = b + b_1(E/P)_t + b_2(1/P)_t + b_3(Pi/P)_t + r, \text{ where}$$

Li/P is the ratio of labor force in age-sex group i to total working-age population;

E/P is the aggregate employment-population ratio;

X/P is the ratio of new unemployment compensation exhaustions to total population;

$1/P$ is the reciprocal of total population;

Pi/P is the ratio of population in group i to total population;

Ei/P is the ratio of employment in group i to total population; and r is a residual-error term.

In a third equation the authors explained the exhaustions ratio in the current period as a function of lagged employment and lagged exhaustions ratios.

The above coefficient a_1 captures the response of group labor force to total employment, while b_1 captures the response of group employment to total employment. The reciprocal of population accounts for trend in the dependent variables in both the labor force and employment equations, while the variable Pi/P measures the effect of relative population shifts. The exhaustions ratio attempts to take account of the pressure on additional workers to enter the labor force before unemployed primary workers use up their unemployment benefits.

Consistent with earlier findings [2] [3] [4] [5] [6], the authors found

that the labor force ratios of marginal workers were strongly and positively related to aggregate employment, while the labor force ratios of prime-age males were relatively autonomous. The employment of all age-sex groups was shown to benefit in varying degrees from rising aggregate employment. Combining the results of the labor force and employment equations yielded the net unemployment outcome, which in the authors simulation clearly showed the growing disadvantage of marginal workers vis-à-vis primary workers.

Of main concern here are the age-sex employment equations, particularly the magnitude of the coefficient b_1 which captures the response of group employment to total employment. The Dernburg-Strand correlations were run on the period 1953-62, but the average total employment-population ratio in the regression period was below its 1955-57 levels when the overall (officially reported) unemployment rate was about 4 per cent. The value of b_1 in the employment equations is in fact consistent with a total unemployment rate in the decade averaging 5.2 per cent. It is apparent, therefore, that b_1 is measuring the response of group employment to total employment in a *loose* labor market characterized by high overall unemployment. Nevertheless, the authors drew upon this coefficient to simulate employment by age and sex in a *tight* labor market characterized by an assumed 4 per cent total unemployment rate. By so doing, they are implicitly assuming that the response of group employment to total employment does not vary in different stages of the cycle. Since the correctness or incorrectness of this assumption is critical in estimating the distribution of both employment and unemployment, it should not go unchallenged. Contrary to Dernburg and Strand's implicit assumption, one might well expect the relation of group employment to total employment to vary by stage of cycle.

To give one illustration: suppose that, as the economy moves from a 5 per cent to a 4 per cent or lower total unemployment rate, the available supply of experienced primary workers begins to grow short. At some point, to satisfy their labor needs, employers step up their inservice training programs and accelerate the upgrading of available marginal workers. At the same time, as more jobs become available, workers may become more willing to take advantage of education and training opportunities. If such adjustments are triggered or accelerated by a tight market situation, then one would expect employment to flow more rapidly toward marginal workers as they are substituted for scarce primary workers. Hence, the coefficient b_1 in eq. (2) would be greater for marginal workers in a tight market than in a loose market, and smaller for primary workers in a tight market than in a loose market. (The less apparent possibility that the response of labor force to total employment might vary in different stages of the cycle, which would also influence unemployment, will be dealt with below.) Other things equal, a larger share of total employment going to marginal workers in periods of low overall unemployment would reduce their unemployment relative to primary workers. In this event, the estimated "full employment" distribution of unemployment in 1954 and 1962 could be quite different from the Dernburg-Strand results.

The hypothesis that group employment ratios *vary* in relation to total em-

ployment ratios in different stages of the cycle can be tested by dividing up the postwar employment experience into cycle stages, with each stage representing a different degree of labor market tightness. For this purpose the following simple variation of the Dernburg-Strand employment equation was tried, using seasonally adjusted quarterly data for the period 1947(Q4)-1965(Q1):

$$(3) \quad (E+A/P)_t = a + b_1(E+A/P)_I + b_2(E+A/P)_{II} \dots + b_5(E+A/P)_V + b_6T,$$

where A is armed forces, T is a trend term, the numerals I-IV referring to successive stages of employment expansion, with stage V including recessions. Thus, $(E+A/P)_I = (E+A/P)$ in those selected periods of the cycle designated as stage I and $(E+A/P)_I = 0$ in all other periods; $(E+A/P)_{II} = (E+A/P)$ in stage II and $(E+A/P)_{II} = 0$ in all other periods; etc. A given stage can include observations from more than one employment cycle, in which case the character of demand in the separate cycles is averaged out to some extent. In order to gain sufficient observations for each of the independent employment variables, the analysis was extended back to 1947 and forward to 1965. Since this longer period contains the Korean War, armed forces were added to employment in an attempt to correct for the distortions evident in the employment data in the early 1950's, which amounts to the assumption that most persons in the armed forces would have been otherwise employed. The inclusion of armed forces does not seriously affect the net regression coefficients in nonwar periods where fluctuations in employment dominate.

Partly because of the ready availability of certain data, eq. (3) differs in several respects from Dernburg and Strand's employment equation (aside from the stage-of-cycle divisions). But these differences are restricted to population or trend expressions which change but gradually over time, and which are generally not correlated with the business cycle. Specifically, eq. (3) ignores the Dernburg-Strand population variable P_i/P ; uses T rather than $1/P$ for trend; and expresses group population in the denominator of the dependent variable in place of Dernburg and Strand's total population. There is no reason to expect that these specification differences, which involve secular influences only, would affect the relative difference between the stage-of-cycle coefficients $b_1 \dots b_5$. Accordingly, of sole concern here is simply the question of whether or not there is any significant difference *between* the stage-of-cycle coefficients in each age-sex group. True, the addition of secular variables or their respecification in the stage equation would no doubt influence the *level* of the net regression coefficients, so no conclusions will be drawn based on such levels in the stage equations.

A description of the five cycle stages used in eq. (3) follows. The selection of stages was guided by observing the behavior of both the aggregate employment-population ratio and the total unemployment rate as indicators of labor market tightness. In the four expansion stages the aggregate employment ratio mostly rises, while in recession it mostly declines. Over the postwar period it ranged between 54.1 and 57.8 per cent.

Stage I. This first stage of expansion includes 15 quarters from three separate cycles: 1950(Q1)-1950(Q2); 1958(Q3)-1959(Q1); and 1961(Q3)-(1963)(Q4). The aggregate employment ratio in these quarters increased from slightly over 54 per cent to about 55 per cent, averaging 54.4 per cent. (Observations from the initial stages of the 1947-48 and 1954-55 expansions are excluded here because the aggregate employment ratio in those periods was predominantly above the 55 per cent upper range of acceptance for this stage.) The total unemployment rate in this stage declined from a high of 7.3 per cent to a low of 5.5 per cent, averaging 6.0 per cent.

Stage II. This stage consists of 15 observations from four postwar expansions: 1950(Q3)-1950(Q4); 1954(Q4)-1955(Q2); 1959(Q2)-1960(Q2); and 1964(Q1)-1965(Q1). The range of the aggregate employment ratio is roughly between 55 and 56 per cent (for which the 1954-1955 expansion period now qualifies). The aggregate employment ratio averaged 55.2 per cent in this phase, indicating a cluster of values around the low end of the range. The unemployment rate declined within a range of 5.4 to 4.2 per cent, averaging 5.0 per cent.

Stage III. Included here are the 14 quarters 1947(Q4)-1948(Q4) and 1955(Q3)-1957(Q3). That the 1948 period is included in this relatively late stage reflects both the strength of aggregate demand and the choice of a starting date for the analysis. In this phase the aggregate employment ratio fluctuated in the 56 to 57 per cent range, averaging 56.5 per cent. At the same time the unemployment rate varied in a narrow range between 4.3 per cent and 3.8 per cent, averaging 4.1 per cent. This stage represents a relatively tight labor market in which the 1955-1957 experience dominates.

Stage IV. This continuous 11 quarter period from 1951(Q1)-1953(Q3) represents the tightest postwar labor market, and includes the abnormalities of the Korean period. In this phase the aggregate employment ratio increased from 57 to nearly 58 per cent, averaging 57.2 per cent. Conversely, the unemployment rate fell from 3.5 per cent to nearly 2.5 per cent, and averaged 3.0 per cent.

Stage V. This final stage includes 15 quarters taken from four postwar recessions: 1949(Q1)-1949(Q4); 1953(Q4)-1954(Q3); 1957(Q4)-1958(Q2); and 1960(Q3)-1961(Q2). The aggregate employment ratio declined sharply to a recession low of about 54 per cent, and averaged 55 per cent over the 15 quarters, while the unemployment rate rose from a low of 3.7 per cent to a high of nearly 7.5 per cent, averaging 6.0 per cent.

The results of this model are shown in the table. The regression coefficients of only one age-sex equation, females age 20-24, are not statistically significant. The fact that the cyclical regression coefficients for this group are negative (compared to Dernburg and Strand's positive result) reflects the incomplete specification of the stage model. Had the stage equations been specified in the manner of Dernburg and Strand, including the variable P_i/P , the cyclical regression coefficients for females age 20-24 would probably have been positive. But, as stated earlier, the main interest here is the extent of difference between the stage-of-cycle coefficients, not their levels. Further com-

parisons of these equations to the Dernburg-Strand findings would not be particularly enlightening because of differences in both model specification and the length of the regression period.

Turning to the extent of similarity or difference between the the net regression coefficients $b_1 \dots b_6$ in each group in the table, it is apparent by even casual observation that the coefficients are not significantly different from one another in all stages of the cycle. I would add that this is also true if trend is eliminated from the stage equation, and if the model is based on first differ-

ences. Nor are there significant differences when the independent variables are regrouped into fewer broader stages in order to increase the number of observations in each stage.

Thus, it appears that substitution among employment groups, insofar as is reflected in the relation of group employment to total employment cyclically, does not accelerate in a tight market, but is a steady gradual process throughout all stages of the cycle. Since the relationship tested does not vary throughout the cycle, it can properly be expressed in equation form by combining all observations of the aggregate employment ratio in a single independent variable as Dernburg and Strand did. The hypothesis of a short-run nonhomogeneous adjustment mechanism between age-sex specific and total employment ratios is tentatively rejected.

But an equilibrating mechanism in the employment market can also be of secular nature, as might be further indicated by the presence of trend in the above cyclical regression coefficients $b_1 \dots b_6$. For example, a significant positive trend in the cyclical coefficients of young, old, and adult female workers in periods of rising demand could lessen the degree of divergence in the estimated distribution of unemployment, and negate the Dernburg-Strand finding of a worsening structure of unemployment rates based mainly on a cyclical analysis. But a test showed that such is not the case. For young and old workers the (linear) trend in the cyclical regression coefficients was either negative or not statistically significant. Not surprisingly, there was a positive trend in the regression coefficients for most adult women who are an increasing fraction of total employment. But women also had a positive and offsetting trend value in their cyclical regression coefficients on the labor force side (i.e., when L is substituted for E in the dependent variable of the above stage model), which *ceteris paribus* leaves their relative unemployment position unimproved. The residual values from the employment equations for these groups appeared essentially noncyclical and unrelated to other economic variables such as wages or hours, but these variables were not explicitly included in the model.

If the labor supply sensitivity of marginal workers to rising demand should lessen as full employment is approached or attained, then their labor force would grow less rapidly relative to employment, which would exert downward pressure on their unemployment rates. But this seems unlikely. It would be more reasonable to suppose that the labor supply sensitivity of these groups would remain the same, or possibly increase in successive stages of expansion as job opportunities improve. Analysis of scatter diagrams of labor force-population ratios against employment-population ratios indicates an unchanging cyclical relationship, as do the results of substituting labor force for employment in the dependent variable of the above stage equation. Trends in the cyclical regression coefficients for young and old workers in the labor force-employment relation were not statistically significant.

In summary, the foregoing results tend to confirm the Dernburg-Strand as well as my own earlier finding [3] that adjustments on the employment (demand) side of the labor market have not kept up with shifts on the labor

force (supply) side, indicating a worsening distribution of unemployment rates under hypothetical conditions of relative full employment.

Forecasting and Analysis with an Econometric Model: Comment

In the March 1962 issue of this *Review*, Professor Suits¹ discussed the University of Michigan's econometric model and its use as a predictive tool. This note presents the results of tests which were designed to evaluate the model's forecasting performance. Before presenting these results, it is important to consider the methods which may be utilized to evaluate the forecasting performance of econometric models, for there is no consensus on *the one* best procedure.

I. Evaluation Procedures and Concepts

The first distinction is between *ex post* and *ex ante* forecasts. In *ex ante* forecasts the *true* values of both the exogenous or lagged endogenous variables are not known at the time that the forecast is made and must be estimated. In a forecast prepared in the fourth quarter of a year for the following year, for

¹We may also be interested in testing the predictive performance of only a portion of a model. In this case, we would be interested in evaluating the predictive performance of a single equation, say, that explaining the behavior of automobile sales. The appropriate procedure in this case is to utilize the structural equation explaining automobile consumption.

example, some of the data are not yet available and even the quarterly or other available figures may be preliminary and subject to substantial revision. Observed forecasting errors in this case may be due either to an incorrect specification of the model or to errors in the estimates of the predetermined variables.

Ex post forecasts use the actual values of the predetermined variables to calculate the predicted values of the endogenous variables. Any errors which result are therefore attributable only to the model itself. These *ex post* estimates may be obtained either for the sample period or for elapsed time periods beyond the sample when the values of the predetermined variables are known. To test the predictive performance of a model in this manner it might be preferable to use data beyond the period of fit, for if the *ex post extrapolations* yielded good predictions, more confidence could be placed in the model's ability to predict.

While it has been argued that the "true test" of a model is its ability to forecast *ex ante*, it is necessary to utilize the *ex post* approach to properly evaluate a model. It can then be determined whether the forecast errors resulted from the model or from incorrect data projections. In addition, it is possible to determine whether the *ex ante* forecast was "correct" due to offsetting errors within the projections and/or the model. In other words, we can distinguish between the ability of the analyst in estimating the predetermined variables and that of the model in simulating the economy.

Another problem arises in the evaluation of a model: Given the actual and either the *ex ante* or *ex post* forecasts, how can the accuracy be determined? A number of alternative criteria may be used to determine the accuracy of a forecast. These criteria include (1) the percentage of turning points in business activity which are forecast correctly, (2) the degree to which the model's rates of change corresponded to the direction and extent of the observed changes, and (3) the performance of the model relative to some naive method of forecasting.

It is inappropriate merely to count the number of true turning points forecast for two reasons. First, a model which is expected to predict quantitatively should be judged on that basis and attention should not merely be confined to the few turns which occurred. In addition, there is the question of whether a model which predicts "a miniscule advance" when a miniscule decline occurs can be judged as being completely wrong. In other words, a 0, 1 scoring system for accuracy is inappropriate because the extent of the error matters. A method which utilizes information about the absolute discrepancy between the forecast and the observed change should be employed, for this also permits comparison of a particular model's forecast with the accuracy of other forecasting procedures and naive methods.

One such measure is Theil's [2] inequality coefficient:²

² Theil indicates that his coefficient, unlike the standard deviation of the forecasting errors, has the advantage that it also covers the case in which the forecasts are consistently over- or underestimated. He also shows that the *U* coefficient can be decomposed into three components to determine the sources of error.

$$(1) \quad U = \frac{\sqrt{\frac{1}{n} \sum (P_i - A_i)^2}}{\sqrt{\frac{1}{n} \sum P_i^2} + \sqrt{\frac{1}{n} \sum A_i^2}}$$

where P_i and A_i are the predicted and actual values respectively. This coefficient is confined to the interval between 0 and 1 with a value of 0 indicating perfect prediction and a value of 1 showing perfect inequality.

The U coefficient may also be calculated for forecasts which are generated by the two naive models;

$$(2) \quad X_t = X_{t-1} \quad \text{and}$$

$$(3) \quad (X_t - X_{t-1}) = (X_{t-1} - X_{t-2}).$$

If forecasts are made in terms of first differences, the predictions generated by the first naive model are always identical to zero

$$(4) \quad (\text{i.e., } \Delta X_t = 0 \quad \text{or} \quad P_t = 0).$$

Consequently, the U coefficient for this naive model will always assume its largest possible value, 1. The predictive performance of any forecasting model which also predicts changes will *a fortiori* always be equal to or better than that of the first naive model. However, predicted changes which are obtained from the second naive model do not automatically generate a U coefficient which approaches either of its limits. Since it is expected that the accuracy of an econometric model will exceed that of naive methods, a model's U coefficient may be compared with a relevant standard, the U coefficient of the second naive model. While no rigorous test has been developed to judge whether the difference between two U coefficients is statistically significant, the U coefficient of the model should be lower than that of the naive method.

II. Evaluation of the Suits Model

There are several ways in which the Suits model will be evaluated. First, the forecast *changes* in GNP for a number of years are compared with the observed *changes* by means of the U test. The actual values of the predetermined variables for 1962 are then utilized with the inverse matrix which Suits published to determine the accuracy of the 1962 *ex post* forecast. Any errors are then attributable to the model and not to misestimates of the predetermined variables. Finally, the inverse matrix and predetermined variables contained in the 1962 model are used to generate *ex post* predictions for 1964 by assigning the actual 1964 values to the predetermined variables. This procedure tests whether the structure of the 1962 model was applicable to the 1964 economy.

Suits has prepared a table of the observed and predicted changes of GNP generated by his model for the years 1953-1964. These data may be used for

the *U* test and are presented in Table 1. The forecasts of Table 1 are the predicted changes which were presented for a given year in November of the previous year based on data for earlier months. They are *ex ante* forecasts and not the *ex post* internal forecasts which would be generated by the present model if the actual values for that year were assigned to the predetermined variables. Second, the predicted changes of Table 1 often differ quite markedly from the forecasts and/or the differences between the forecasts and actual changes which Suits presented in his AER article [1, p. 123]. The discrepancy is the result of including the error in the previous year's estimated level in the prediction for the subsequent year. This error is included in the article but not in Table 1 where only the predicted *changes* are presented. The proper ap-

TABLE 1—CHANGES IN GROSS NATIONAL PRODUCT, FORECAST AND ACTUAL
(Billions of 1954 dollars)

Year	Forecast	Actual
1953	13.0	15.5
1954	-4.5	-5.9
1955	4.4	29.6
1956	9.0	8.2
1957	9.1	7.7
1958	-2.9	-7.3

proach, as Suits himself suggests, is to compare only the actual and forecast changes. This is what Table 1 does.

A comparison of the observed and predicted changes for 1953-1964 indicates that the model had only two serious failures. The upswings of 1955 and 1959 were badly underestimated. In addition there also seems to be a modest underestimate of the 1958 decline and 1960 movement. Otherwise, the model appears to have performed remarkably well. This result was confirmed when the *U* test was applied to the forecasts and actual changes. The inequality coefficient for the model was .30 whereas the naive model's coefficient was .57. Thus, using this test the Suits model must be considered superior to naive methods.³

The next test was to insert the actual 1962 values of the predetermined

³ In 1965, there was again an underestimate of the increase in GNP. The predicted increase was \$15.8 billion, the actual was \$24.6 billion. These data became available after the *U* coefficients had been calculated for 1953-1964. If this observation had been included the difference between the two *U* coefficients would have narrowed since the naive prediction for 1965 was \$24.1 billion.

variables into the 1962 model⁴ and to generate the *ex post* predictions. The *ex post* predictions are substantially higher than the *ex ante* forecasts of the model and are also larger than the actual changes which occurred. The model itself is only designed to generate forecasts of the change in privately produced GNP, exclusive of imputed services. Consequently the comparisons of the *ex post* forecasts must always be made with similarly defined actual changes in the relevant variables. For instance, the actual increase in GNP which occurred in 1962 was \$28.5 billion (in 1954 dollars). This must be compared with the *ex ante* forecast of \$27.5 billion and the *ex post* prediction of \$35 billion. It is thus apparent that the *ex ante* forecast was much more accurate than the *ex post* prediction. The entire amount of this \$6.5 billion discrepancy between the *ex post* prediction and the actual change is attributable to the model's internal errors in forecasting privately produced GNP, exclusive of services. The errors are not attributable to the exogenous variables such as housing, plant and equipment, exports, government expenditures, or services, for they were assigned their actual values. This information is presented in an aggregated form in Table 2 and in a disaggregated form in Table 3.

Several exogenous variables were underestimated in the *ex ante* forecasts, thus producing the near perfect correspondence between that forecast and the actual change. For instance, the *ex ante* estimates for exports, plant and equipment, and housing were \$0.0, \$1.3, and \$0.1 billion respectively. The actual values were \$1.7, \$3.0, and \$1.9 billion respectively. (These data are shown in Table 3). On the other hand, government purchases of goods and services were overestimated by more than \$2 billion. Another important *ex ante* underestimate was the increase in OASDI transfer payments. These were estimated at no change; an increase of \$1.8 billion occurred. This contributed an increase of about \$2 billion to gross private GNP. The evidence thus indicates that when the actual values of the predetermined variables are inserted into the model that an overestimate of the increase in GNP is predicted.

This overestimate can also be observed in Table 3 where the *ex ante* and *ex post* estimates of changes in the disaggregated components of GNP are compared with the actually observed changes. The size of the discrepancy is the same as in Table 1, as it must be, for the same model and inverse matrix were used. However, the interesting phenomenon to be noted involves the predicted change in consumption which is larger than the predicted change in disposable income.⁵ The *ex post* predicted change in consumption was \$20.5 billion and that for income was \$17.7 billion. This indicates that the other determinants of consumption expenditures, such as liquid assets, might have been given too much weight in the model.

It is also important to remember that data are constantly being revised and it is difficult to know which are the "actual" values of the predetermined variables that should be inserted in the model. In our case, we have used as the 1962 values the data for 1962 which were available in 1964. Since these re-

⁴We refer to the Michigan model by year because the model is constantly being revised. The 1962 model was the one which was published in this *Review* in March 1962.

⁵Both consumption and income changes are net of imputations.

TABLE 2—ESTIMATES OF CHANGES IN GROSS NATIONAL PRODUCT FOR 1962: SUITS'
EX ANTE FORECAST, EX POST FORECAST, AND ACTUAL CHANGE

(Billions of 1954 dollars)

	Suits		Actual Change
	<i>Ex Ante</i> Forecast	<i>Ex Post</i> Forecast	
Change in privately produced GNP (exclusive of imputed services)	25.3	31.3	24.8
Change in income originating in government	0.9 ^a	1.8 ^a	1.8 ^a
Change in imputed service	1.5	1.9	1.9
Total change in GNP	27.7 ^b	35.0	28.5

^a This figure was obtained from Suits' article by subtracting Suits' estimate of government purchases from the private sector from total government purchases of goods and services. The sum of changes in government purchases from the private sector plus the change in government wages is greater than the change in government purchases of goods and services. It is due to changes in government imports and sales to the private sector.

^b This figure differs from Suits' figure of 27.5 [1] due to rounding errors.

^c It was impossible to obtain data of government purchases of services from the private sector. Consequently, all of the increase in government purchases of services was attributed to the government sector. This somewhat reduces the *ex post* forecasts of the Suits model and makes the comparison more favorable to the model. The figure which is presented (1.8), is the change in government wage payments to its employees. The figure for government purchases from the private sector which was used in the reduced form equation was obtained by subtracting this figure from total government purchases of goods and services. This estimate of government purchases from the private sector is somewhat lower than what it must have been in actuality (see footnote^a). The *ex post* estimate of privately generated GNP would have been increased by 1.304—multiplied by this discrepancy, while the actual data would only have been changed by the amount of this discrepancy.

vised data might not be applicable to the 1962 model, it should be noted that this approach has introduced a possible source of error into the evaluation. While this bias is likely to be inconsequential, it must still be noted.

Two additional tests of the model were made. First, the 1962 *ex post* residuals of the structural equations of the 1962 model were examined to determine whether the biases were also observed in these equations. Finally, the 1962 model was utilized to make *ex post* predictions for 1964. Both tests indicated that the 1962 version of the model tended to overestimate changes in GNP.

The analysis (Table 4) of the residuals of the structural equations indicated that all of the consumption expenditure equations were uniformly overestimated or biased. The inventory and import functions, however, yielded excellent predictions. This evidence once again indicates that structural change has occurred and that the inclusion of the liquid asset variable may cause the overestimates. It is also interesting to note that the 1963 version of the model did not include liquid assets within the consumption expenditure equations, but this variable is reintroduced in several consumption equations in the 1964 version of the model and in the automobile equation of the 1966 version.

TABLE 3—ESTIMATES OF CHANGE IN GROSS NATIONAL PRODUCT AND COMPONENTS
IN SUITS' EX ANTE AND EX POST FORECASTS, AND ACTUAL CHANGES IN
GROSS NATIONAL PRODUCT AND COMPONENTS

(Billions of 1954 dollars)

	Suits 1962 Forecast		Actual
	<i>Ex Ante</i>	<i>Ex Post</i>

Nondurable inventory	0.1	0.2	-0.1
Imports	1.9	2.0	-0.1

When the 1962 version of the Michigan model was utilized to generate *ex post* predictions for 1964, the same overestimates were obtained. This prediction was calculated by assigning the actual 1964 values to the predetermined and exogenous variables which are contained in the 1962 model. The model predicted a \$33.7 billion (1954 dollars) increase for 1964. This must be compared with an actual change of \$23.4 billion. Thus, all the evidence seems to indicate that the 1962 version of the Michigan model had a tendency to generate *ex post* predictions which overestimated changes in GNP.

III. Conclusions

On the basis of our evaluation of the model we may conclude: (1) A comparison on the basis of U coefficients indicated that the model performed substantially better than the naive methods; (2) The *ex ante* forecast for 1962 is substantially better than the *ex post*, which overestimates changes in GNP; (3) The residuals of the structural consumption equations are all positive indicating that structural bias may have existed in this version of the model; the *ex post* overestimate of 1964's change as predicted by the 1962 model reinforces this conclusion; (4) Finally, it should be noted that the observations apply only to the 1962 version of the model. Later versions of the model have not been evaluated.

Errata

In the September 1966 issue, Nissan Liviatan's article on "Multiperiod Future Consumption as an Aggregate" contained some printing errors, which are corrected below:

P. 830, line 11, for: $(1+r_1)C_0$, read: $(1+r_1^0)C_0$.

P. 831, line 1, for: $1/(1+r^0)$, read: $1/(1+r_1^0)$.

P. 833, first equation, delete: $\equiv H(C_1, \dots, C_n)$.

P. 835, equation (5), for: $T(C_1, \dots, C_n; K_0)$, read: $T(C_0, C_1, \dots, C_n; K_0)$.

P. 835, para. 2, line 12, for: $f'(F_0 - C_0)f'(K_1 - C_1)$
read: $f'(K_0 - C_0)f'(K_1 - C_1)$.

P. 839, para. 3, line 12, for: value of H , read: value of D .

BOOK REVIEWS

General Economics; Methodology

Economic Advice and Presidential Leadership: The Council of Economic Advisers. By EDWARD S. FLASH, JR. New York: Columbia University Press, 1965. Pp. x, 382. \$8.95.

One wonders whether, on preliminary form, there was ever a more unprising piece of legislation than the Employment Act of 1946. The title it was a hedge; reference to full employment was too controversial. Any mention of methods by which employment would be sustained was avoided. To hint at deficit financing would have been fatal. Three economic advisers were provided which, it could be foreseen, was a certain formula for endless disagreement. They had no visible executive authority. A Congressional Committee was authorized but with no legislative powers, a point emphasized in its original name. As a substitute for solid function, an impressive system of reports was provided for. I remember discussing the legislation in 1946 with Milton Gilbert who was one of its architects. We agreed that it was principally a gesture though probably a useful one. He thought it more useful than I did.

Yet in retrospect the Employment Act appears as the most important single piece of economic legislation of the postwar years. The Council of Economic Advisers which it created has, a few early months apart, functioned harmoniously as a powerful general staff on economic policy. It has far outstripped the Secretary of Commerce and the Federal Reserve Board in influence. Probably it is now more powerful than the Treasury. The Joint Economic Committee, as it has been retitled, if a less spectacular success, is the most respectable forum for economic discussion in the Congress. How did it come about?

I should suppose there are quite a few reasons. The President needed economic advice. The CEA gave him men of his own selection committed to the success of his administration. Short terms for both members and staff (stabilized by such admirable civil servants as David Lusher) prevented hardening of the arteries. Chairmen were allowed, in general, to choose their own leagues. Economists joining the Council and staff uniformly abandoned the occupational tendency to be fancy and worked in a tradition of careful, empirically-based judgment. A strong sense of professionalism on the part of Arthur Burns protected the work of the Council and staff from the destructive prejudices of such Paleozoic statesmen as Sinclair Weeks and George Humphreys during the Republican years. And two men of remarkable energy and purpose—Leon Keyserling and Walter Heller—made the Council exceedingly hard to ignore under the Democrats.

This brings me at long last to Professor Flash who has written a comprehensive history of the CEA which is billed also as an analysis of the sources of its power. It is reasonably good. The author has gone over the record with care. There is a wealth of chronological detail on the important decisions

also on some of the unimportant ones. He has a competent view of the economic issues.

Yet it isn't perfect. For one thing, a solemn, even lugubrious effort to get at the organizational and administrative verities keeps dulling his points. One of his points is that, in dealing with the President, the Council derives power from its knowledge of economics. It takes a long time to say this. Various of the other sources of the Council's success mentioned above can be found. But again they have to be excavated from under the words. There is also far too much detail on the coming and going of staff or the not terribly historic observations of the members. Nor does everything get in. I should have thought that one of the fairly important issues in the tax reduction debate of 1962 was whether it wouldn't durably impair allocation as between the public and private sectors and be irreversible. If so, more spending would be better. In any case, these contentions came up, some will recall rather tediously, at the sessions I attended.

Finally, the author sometimes allows words not so much to obscure meaning as to eliminate it. Here is part of his conclusion:

If the experiences of the Council of Economic Advisers are indicative, the knowledge-power relationship implicit in the advisory function is both important and enlightening, and this study of the Council's operations should contribute to a broader understanding of that relationship. It should in all probability suggest an analytical approach that isolates and identifies the operating dynamics and intricacies of the relationship between knowledge and power, adviser and leader.

If this means what it seems to mean, I venture to think that it doesn't mean anything at all. Flash is a man of obvious intelligence. It is too bad that the more bogus traditions of scholarship did not allow him to write a straightforward and succinct history with no pretense.

J. K. GALBRAITH

Harvard University

Economics: Principles of Income, Price and Growth. By R. MURRAY HAVENS, JOHN S. HENDERSON, DALE L. CRAMER. New York and London: The Macmillan Company, 1966. Pp. xvi, 623.

This is a competent principles text for college level courses. It has deficiencies, like all texts. The nonpecuniary justification for another close substitute, like this one, must therefore run in terms of nuances that appeal to the tastes of particular instructors or to students. One can certainly discount at the outset, however, the authors' assertions that the assumptions employed are "realistic." Almost everybody claims this metaphysical virtue.

According to the blurb on the cover, the product is differentiated chiefly by "particular attention to the concept of growth . . . examined as an integral part of the whole subject rather than as a separate entity." I agree that the book scores on this account, a feature that will become increasingly popular in introductory texts, it seems to me. In addition to a modest, helpful interweaving of growth aspects at a number of relevant points, there is an adequate spe-

cial section on the growth topic as such. On the other hand, the book lacks even a modicum on the growth problems of less-developed economies. This is a serious omission to me; but omissions of particular areas of the subject are, admittedly, a matter of taste.

Why not contrast this omission with the book's more than 100 pages (one-sixth of the total) of capable discussion on international "trade"? Isn't this too heavy a weight on that special topic? Doesn't such weight reflect the interests of the authors rather than the "balanced needs" of students? Is it justified, as the authors claim, by "the growing importance of the international sector" (like merchandise exports relative to GNP in 1929 equal .05, and in 1965 equal .04)?

Two other features of the work seem to me important for an appraisal: (1) national income determination is tied in with monetary theory, and (2) the presentation of price theory (properly called "value theory") is built largely around imperfect competition rather than pure competition so far as the production side of the market is concerned. Both of these are to be hailed. The separation that has so long prevailed in textbooks between income determination theory and monetary theory has caused endless technical confusion in the minds of students; and the detailed elaboration of the purely competitive theory of the firm and the industry, presented as positive theory and left on the level of first approximation, has left generations of students baffled and repelled by the subject. Let's have more of the different approach in this textbook.

Economics a la Messrs. Havens, Henderson, and Cramer moves from macro to micro, from price theory to distribution theory, and from value and distribution to its two, and only two, applied areas: international economics and growth. I doubt that rearrangement by an instructor would work out. You have to take it this way or leave it, a framework probably approved by most.

This text is a serious candidate, and the specific adverse criticisms among these that follow are not intended to alter that judgment. The macro discussion proceeds, despite an explicit treatment in one of the several "high level" appendixes, without benefit of the distinction between scheduled and realized magnitudes. As a result, to take one example, the concept of aggregate supply is initially (e.g., pp. 53, 55) thoroughly clobbered: the poor reader is told that it is the 45° line, and that it is simply "real income." Later, things are patched up, and another type of aggregate supply function, having a different purpose, is introduced, but I believe the damage will by then have been done. The effective lack of a schedule concept appears to me to be the most serious technical weakness of the book. In an "aside," the authors venture the judgment that the use of scheduled magnitudes, as distinguished from *ex post*, involves "misplaced ingenuity"! On the micro level, the schedule seems to have at least a nominal existence (e.g., pp. 38, 42).

On the positive side, in the theory of production and revenue, the physical input-output relationships, on the assumption of short-run diminishing returns, are first presented, *then* the *same* cost functions are used in connection with the construction of the standard revenue relationships. This is excellent pedagogy. How can a student understand the shape of the standard cost functions if he or she doesn't yet know the input-output functions from which

those cost functions are drawn? Probably only Samuelson can unravel this pedagogical mystery. Unfortunately, explicit reference to a production function is made only much later (pp. 381 ff.), and not tied in with the earlier input-output, diminishing returns table.

Now for a grab-bag of running comments: the investment concept bypasses human training, despite the ground swell of current argument in favor of its inclusion; the assertion of a tendency toward equilibrium is unfortunately at times considered to make equilibrium empirically the "most likely value"; the obsolete term "business man" is used to refer to the top decision-making individuals in a contemporary firm; the owners of corporations make income payments to factors (via representative democracy?); pure profits are "connected" with uncertainty, but just how is still a mystery (and it ought to be told); the treatment of government deficits as savings offset is made bland by a lack of reference to historical controversy; differentiated oligopoly suffers at the expense of pure oligopoly; the definition of oligopoly spans 14 pages (fewness on page 300, recognition of mutual interdependence on page 314); "industry equilibrium under oligopoly" is, perhaps not unreasonably, a heading without a treatment; clock time and analytical time are not clearly distinguished; changes in scale and in technology are not analytically disengaged; the long-run planning curve of the firm turns up in time to save competition, and for the same old story-book reason (diseconomies of large management); the creation of deposits is explained by using the excellent T account method; and there is, happily, a moderate amount of factual and institutional material despite the authors' allegation that such material is minimized. There is, as usual, no analysis of urban problems, or of regional growth phenomena, and no population or location theory.

This book is rather nationalistic, even though it has a big section on international economics. I think the special areas section ought to treat not only the problems of development of less developed countries, but also comparative systems. It could be taken in part from the international trade section. We all have separate courses in that important subject. The rest of the required space could be obtained by making the book larger.

Like all texts, this has its deficiencies; but it is in general a competent candidate.

HAROLD G. VATTER

Portland State College

Economic Enquiry in Australia. By CRAUFURD D. W. GOODWIN. Duke University Commonwealth-Studies Center Publication No. 24. Durham: Duke University Press, 1966. Pp. xv, 659. \$12.50.

Professor Goodwin has made a comprehensive study of Australian economic enquiry, both popular and scientific, from the early colonial period to the onset of the Great Depression in 1929. In presenting his findings he has adopted a similar formula to that employed in his companion volume on Canadian economic thought, published under the same auspices in 1961. The material is divided into two sections, the first of which deals with the application of imported economic ideas to the policy problems of a developing country,

while the second charts the emergence of professional economic studies in Australia. The only other work with which this book can usefully be compared is Professor La Nauze's *Political Economy in Australia* (1949), which is a more concise work concentrating on three figures, Jevons, Hearn, and Syme, whose reputations extend beyond Australia. Goodwin's main object has been "to identify the presence of ideas and methods of enquiry rather than to assess the relative importance of individual contributors." Some incidental evaluations are made of the quality of reasoning and insight displayed in discussion, but for the most part he is less concerned with the history of economic analysis than with the history of economic opinion and theory in its relationship to policy and environment. Since he believes that the economic attitudes which the settlers brought with them or acquired through experience were important in determining the pattern of Australian development, he describes his work as "an essay both in economic history and in the history of economic doctrines."

For much of the nineteenth century, quite understandably, Australian economic literature was the by-product of policy debate, with the works of better-known writers in the mother country and America being used mainly as texts to be drawn on to justify or condemn particular courses of action. In a series of chapters which cover such topics as tariffs, land disposal, money and banking, economic fluctuations, and railway economics, Goodwin documents the wide variety of positions adopted, and the uses made of borrowed theory in Australian controversy. Although the agenda differed somewhat, the Australian policy debates mirror those taking place elsewhere at this time; none of the propositions of neo-classical marginalism, however, seems to have spoken to their condition. It is perhaps surprising to note the extent to which the laissez-faire tradition exerted a continuing, and frequently inhibiting, influence in the new setting.

While much of the literature considered here is ephemeral, in some fields Australia was well served by her economic commentators. This was the case, for example, with railway economics where, despite the limitations of contemporary thinking and technique, the informed public was presented with substantial accounts of the alternative costs and benefits of different types of railway development. The "amateur" in the railway and public utility field, it would seem, performs better than his counterpart in monetary discussion. Though Australia had its share of heretics, the chapter on economic fluctuations shows the tenacity of the doctrine of the impossibility of overproduction. The Australian writers were handicapped by their isolation, by the inadequacies of the existing corpus of knowledge, and by the comparative novelty of their condition. But is the situation so different today when modern communications place the latest techniques at the disposal of developing countries?

Acute problems of arrangement and emphasis are encountered in handling a mass of evidence drawn from popular and semipopular writings over such a large time span, especially where there are no dominant figures or schools of thought to give backbone to the account. Goodwin's method has been to treat each policy topic separately and chronologically. This involves a certain amount of repetition, with the reader having to revert to the beginning of the

period with each new topic. There is also some danger of the reader losing sight of the larger issues posed at the beginning of the study. By the same token, however, the arrangement may be convenient to those who wish to refer to particular questions.

In the second part of the book the rise of an objective science of enquiry is traced. After a lengthy chapter on the collection of economic statistics, Goodwin digresses from his stated aim of not considering individual contributors by drawing attention to the work of two unorthodox writers in the field of macro-economics. The chapters devoted to the struggle to gain recognition for economics in the universities provide interesting comparative material for those with a taste for the history of academic communities. Given opposition from sections of the general public who associated economics with one cause or another which was unacceptable, it is perhaps not surprising that the early curricula should have been so unenterprising; the more adventurous courses were given outside the universities. La Nauze's conclusion that the history of economics in Australian universities during their first sixty years is an "arid story" is amply confirmed.

This was a bold undertaking which adds to our understanding of the transference of economic and social ideas. It is the kind of contribution to intellectual history that only an economist could have made. It may also shed light on Australian economic history, though it must be said that Goodwin is more successful in showing how economic circumstances shaped Australian thinking than in demonstrating the more difficult process by which ideas influence action.

DONALD WINCH

University of Sussex

Economics. By RICHARD G. LIPSEY AND PETER O. STEINER. New York: Harper & Row, 1966. Pp. xxxii, 760.

Does a new textbook have to be significantly different from existing ones to justify its publication? Apparently many economists believe so. Reviewers of textbooks in this journal often begin by describing the features of the new book that justify its publication: it's up-to-date, it uses more or fewer graphs, micro is taught before macro, it contains material gleaned from recent journals, etc. Not only reviewers, but authors and publishers are similarly eager to demonstrate that their new book has something different.

But it is probably more important to know if a new product is substantially similar to existing ones than to know how it differs. Does it do what existing ones do? Is it just about as good or bad? Let me begin then by stating that I believe Lipsey and Steiner is not very different from the *leading* textbooks now in use in the United States to teach elementary economics. It covers the usual topics that most of us consider the elements of economics: micro, macro, international trade, growth, and development. The level of difficulty is about the same. The material is usually well organized, the writing is always lucid. Some people will like the competition better than it, but it should find a substantial group of admirers. And it would be just about as difficult to predict

who will fall into one group and who into the other as it would be to predict who will smoke Kents and who Marlboros.

Lipsev and Steiner, like any good book, has strengths and weaknesses. I can only give generally the things that I liked about it best. The value and distribution sections are second to none. The authors resist better than most implying that economists know more than they really do. No student should put this book down with the feeling that economics is a pat subject. They should have the sense that something has been learned, but that almost nothing is certain. And, if the attitudes of Lipsey and Steiner are contagious, students should be optimistic about the discoveries yet to come from careful scientific enquiry and some of them will be eager to make a contribution.

The authors are more explicitly concerned with methodology than is usually the case. They insist again and again that economics must be concerned with positive rather than normative statements. And this is all to the good. What they fail to do is indicate that this is not easy to do. Economists cannot explore all the implications of any action. They must restrict their attention to important economic effects. And the economist himself must decide what is important and what is economic. In making this decision, values creep in where only analysis is supposed to dwell. Difficulties also exist when the economist tries to restrict his attention to whether a particular policy will achieve its objectives, for who is to decide what the objective of a policy is? If an economist believes that Congressmen vote for minimum-wage laws because they believe that it will lead to their gaining more votes than they will lose, is it his task to sample public opinion to see if the legislators are correct? And even the way a conclusion is stated may determine the reaction to it. For example, the authors argue that the monopolization of an industry may reduce output and raise price. But they could just as well state, assuming full employment of resources, that the monopolization of an industry will lower prices and raise output in the rest of the economy. The reactions to the two ways of stating the conclusion would differ. The economist cannot state every conclusion every possible way; what he thinks ought to be is likely to determine how he states his results.

The book contains some mistakes and sometimes it misleads. The authors argue that, in the absence of rising factor prices, average and marginal cost for a firm are constant in the long run. Since if a firm doubles all inputs it can at least double output, costs will only increase if factor prices increase. This argument misses an essential point. What is at issue is what happens to cost for a firm in the long run. If *everything* is doubled, where there was one firm before there would now be two. The very notion of a firm implies that some thing is fixed. If a firm doubles its productive capacity, it will not, if it is to retain its identity, operate with two chairmen of the board of directors. A farmer can vary his output by adding more inputs; he can double his land, seed fertilizer, etc., and in some societies he can add a wife and have more children. But it would be unrealistic to assume that he can also add a husband.

The reader is told that the purchase of a \$1,000 machine that will last for ten years and that will produce an annual income of \$120 after wage, raw ma

terial, and depreciation costs, yields a 12 per cent return. As they put it, \$120 is 12 per cent of \$1,000.

The authors conclude that a lump-sum tax, a per unit tax, or a tax on accounting profits is entirely passed onto the consumer in the long run in perfect competition. Although they have a superb discussion of economic rent in later chapters, they overlook the burden that will fall on specialized factors.

In Chapters 37 and 41 they argue that changes in relative prices are the crucial factors in achieving equilibrium in the balance of payments. Devaluation cures a balance-of-payments deficit by altering relative prices, not by reducing demand in the devaluing country and raising it elsewhere; what happens to aggregate demand in relation to aggregate supply is not mentioned. Only later, after their presentation of national-income analysis, do they introduce the possibility of correcting a deficit by reducing demand.

Lipsey and Steiner insist that economists cannot validly argue that a twenty per cent reduction in tariffs will raise national income, but they can argue that we are better off today with trade than we would be without it. If they mean by this that, because of obvious cost differences in different countries, economists can argue that world output could be made larger with some trade than with no trade, I suspect that no one would disagree. But they seem to mean that we are clearly better off at present with the existing volume and composition of trade than we would be without any trade. But this conclusion is no more established than the one about the gain from a 20 per cent tariff reduction.

The short-run supply curve for an industry is said to be the horizontal sum of the supply curves of all the firms in the industry. They do not mention that this depends on the unlikely assumption that factor prices are constant to the industry in the short run. They argue that the marginal revenue product of a factor must decline if the demand curve is negatively sloped and if there are diminishing returns, since marginal revenue will decline if the demand curve is negatively sloped. But if elasticity increases as demand decreases, marginal revenue can increase when price falls.

The distinction between the *ex post* and *ex ante* equality of saving and investment is ignored. The necessary equality of saving and investment is not mentioned anywhere. They assume in the beginning of their analysis that inventories are constant. Presumably this assumption is made to avoid this discussion, although the reader is not told why. And in one section of the chapter in which inventories are assumed constant, they are clearly allowed to vary.

Chapter 51 on Government and the Circular Flow of Income is the poorest chapter in the book. The possibility of government financing of deficits by printing money receives virtually no attention. The distinction, from the point of view of the national debt, of financing a deficit by sale of bonds to the Federal Reserve Banks as opposed to sales to the public is ignored. The material in this chapter and the further association of prices with the money supply—Part X is titled “Money, Banking, and Prices”—will, I am sure, leave the impression that an increase in the money supply is necessarily inflationary. If, after reading this book, students were asked to comment on the view that depressions should be cured by government spending, but deficits should be

financed by the sale of bonds rather than the creation of money, since the latter would only be inflationary, the results would be almost universal agreement. The treatment of the burden of the debt in this chapter will raise the hackles of many. Although the authors devote most of their attention to the case in which the sale of bonds leads to a reduction in consumption, they explicitly—ignore the views of Bowen, Davis, and Kopf (this *Review*, September 1960). And why consumption should be altered by the sale of bonds is not even hinted at. The chapter on Household Consumption gives no reason to expect any relationship. They also argue in this chapter that there is a limit to the debt, but their demonstration is wrong. They assume that the government's deficit is equal to 5 per cent of national income every year and that income grows at 2.5 per cent a year. They conclude that eventually interest payments on the debt will exceed the national income, although Domar showed years ago that interest payments as a fraction of the national income would approach twice the rate of interest.

The authors devote considerable attention to the Quantity Theory. In their view this theory asserts that any excess supply of money leads directly to an increase in the demand for commodities; none of the excess supply will appear in the securities markets. I do not know where in the "classical" literature they would find the justification for this proposition. In equilibrium, desired money balances may be proportional to expenditures, but this does not imply that excess money holdings must lead to a direct increase in the demand for commodities. In many versions of Keynes's *General Theory*, prices are proportional to the money supply, if full employment is assumed. Ricardo examined the case in which banks increased the money supply by creating new currency. He concluded that prices would be proportionally higher, but the money did not, in the first instance, lead to an increase in the demand for goods; the money first appeared in the securities markets.

The errors in Lipsey and Steiner do not seriously detract from the book. Who can write 735 pages of economic principles without making a mistake? If economics cannot be learned better from Lipsey and Steiner, it can be learned as well.

ARNOLD COLLERY

Amherst College

Price and Allocation Theory; Income and Employment Theory; Related Empirical Studies; History of Economic Thought

Capital and Growth. By JOHN HICKS. New York and Oxford: Oxford University Press, 1965. Pp. xii, 339. \$5.00.

This book is unmistakably Hicks. It has, naturally enough, the vices of its virtues. Every idea is thought through from first principles, almost as if it had never been thought before; and there are very few references to the literature, even when the literature has taken the problem further than it is carried here. Complicated problems are explained in words of one syllable; and two-sylla-

ble problems are slighted a little. Still, the virtues far outweigh the vices. Anyone who wants to introduce himself or his students to the large volume of recent work on the structure of equilibrium growth will turn to Hicks. This is exposition made into a fine art. And it is more than that; there are some interesting new ideas as well. One could hardly expect otherwise.

The best part of the book, I think, is Part II on Growth Equilibrium. It covers the Robinson-Sraffa-Samuelson theory of steady-state growth with discrete production processes, and covers it with great clarity and understanding. The main tool is the Samuelson factor-price frontier, or wage equation, as Hicks calls it. Among the good things, I mention only a clear statement of the duality between the price and quantity equations—though Hicks does not exploit it fully as Michael Bruno has now done—and a novel treatment of income distribution in steady states. There is a chapter on what Hicks calls *Traverse*, the process of moving from one steady state to another. This chapter doesn't get very far; but it is an intrinsically difficult problem and no one has got much further. Even so, it contains a neat piece of analysis showing that when the "Uzawa condition" is not satisfied, so that the capital-goods industry is more capital-intensive than the consumer-goods industry, there is no full-employment path leading from one steady state to another with a different savings rate, and a correspondingly different growth rate.

In this context, when he comes to introduce saving behavior, Hicks limits himself to the two assumptions that have dominated the discussion so far: savings are proportional either to total output or to profits. It would be more natural to connect savings explicitly with the stock of wealth, in the manner of Modigliani and much of the recent econometric literature. Fixing the wealth-income ratio, say, could hardly affect the characterization of steady states very much, but that sort of saving function could make a considerable difference in the analysis of non-steady state behavior. Indeed, my colleague Karl Shell thinks that this may account for the unstable behavior that has been observed by Hahn in certain multisector economic models with mechanical saving behavior. In such models, the assumption that expectations are fulfilled generates paths that diverge from the steady state, except for very special initial conditions. Shell conjectures that if producers maximize present value and savers maximize utility, full competitive equilibrium leads to the steady state.

It seems clear to me that at this stage of the game the difficult job of studying non-steady state behavior should have the highest priority. Hicks turns away from it with a paragraph that I want to quote at length. "The kind of analysis which has emerged from our discussion of the *Traverse* could no doubt be carried further; but I shall not make any serious effort to carry it further in this book. It would evidently be necessary, if we were to elaborate it, to introduce some particular assumptions about investment policy: to assume that businesses, in carrying out their difficult task of adapting an inappropriate capital stock into something more appropriate, will go about that task in some particular way. But it is hard to see what particular assumption of this kind there can be that is especially deserving of study. Even in macro-

analysis . . . there are no compelling principles that can be relied upon to perform this function; there, however, it was possible to find some simple rules (capital stock adjustment and so on), the consequences of which it was at least of some interest to work out. Similar exercises could presumably be performed, even with a disaggregated model; but it would be blatantly obvious that they would be no more than exercises. Perhaps this is unduly pessimistic; all I ought to say is that I myself do not see any interesting way of taking this analysis further."

Every economic theorist has had that feeling; yet sometimes I think it mistakes the beginning of economics for the end. When we run out of compelling principles, we may have to steel ourselves to settle for merely accurate ones.

Part III is called Optimum Growth. It contains an exposition of the von Neumann model of expansion, a discussion of the Turnpike Theorem, and some remarks on the Ramsey problem, the problem of defining and characterizing an optimal path of capital accumulation. The treatment of the Turnpike Theorem really does succeed in getting at the heart of a complicated result in a clear and elementary way. And the discussion of the von Neumann model is only a bit less successful. These chapters, and the ones preceding, make accessible a whole range of difficult and important modern theory.

The chapter on optimal saving programs is not so good. It does not take sufficient account of the most recent advances in this field, perhaps because many of them are still unpublished. Nor are the less fancy methods Hicks would like to apply really adequate to the task. He criticizes Ramsey and his contemporary followers for the assumption they all make, that consumption bundles at different points of time are independent goods in the usual sense. But it seems a little beside the point to insist that the assumption is not true, because none of those who use it actually believes it. They would gladly substitute a better assumption if the mathematical techniques were available. The important question is whether the theory gives wrong results on that account. It is of course true that an intertemporally additive utility function fails to penalize irregular consumption paths, and fails to penalize falling, as distinct from low, consumption. But since the optimal paths generated under the independence assumption always show smoothly increasing consumption over time, it is hard to believe that introducing those penalties would make a lot of difference.

Part IV, "After Growth Theory," contains two quite independent chapters. The first has to do with the place of money, securities, financial intermediaries and a hierarchy of interest rates in a growing economy. There are some perceptive remarks, but the argument suffers from the absence of Tobin and Gurley-Shaw. The last chapter is one I ought to hold near and dear. It is about the conditions that need to hold in a many-good economy for one to be able to define a "production function" in "labor" and "capital" whose partial derivatives will do the right things. But I am too much of a rank methodological opportunist to care. I have never thought of the macroeconomic production function as a rigorously justifiable concept. In my mind it is either an illuminating

parable, or else a mere device for handling data, to be used so long as it gives good empirical results, and to be abandoned as soon as it doesn't, or as soon as something better comes along.

ROBERT M. SOLOW

Massachusetts Institute of Technology

Theory of Production. By RAGNAR FRISCH. Chicago: Rand McNally; Dordrecht: D. Reidel, 1965. Pp. xiv, 370. \$11.00.

It is good to have Professor Frisch's influential lectures on the theory of production at last available in English. They provide an authoritative restatement of the fundamentals of the classical theory, for a world of many commodities. Elementary mathematics is the natural language, and is much used. The style is crisp, direct, and unashamedly technical. The volume is a treatise rather than a textbook, with few embellishments to entertain the reader, who must be charmed rather by the rhythm of careful and exact reasoning. Occasional eccentricities of terminology and a rather sketchy treatment of the intertemporal and dynamic parts of the theory do little to detract from the evident distinction of the work.

One may, however, regret that it has become available so late. In his preface, Professor Frisch anticipates the charge of being unfashionable. "These good old types of analyses we shall however never be able to dispense with," he says, referring to the marginal analysis. "We will in the end always need to fall back on them." The programming methods of the new economic theory find no place. The appearance of Frisch's book might encourage us to consider whether the older language of production functions and marginal products provides easier methods or more truths than the newer ways.

The lectures are based on three distinctions. First, the distinction between technical and economic considerations; second, the distinction between the quantity-adjuster (or perfect competitor) and the pure monopolist (other cases are left aside in these lectures); third, the distinction between a smooth (everywhere differentiable) production function, and one that is not (called here the distinction between continuity and limitational factors). The one-product producer is studied first. The various technical possibilities of production are explained in detail, with emphasis particularly on the case where production is eventually a decreasing function of any particular factor, and on the technical possibilities that will, when economics is brought upon the scene, lead to constant costs or a U-shaped cost curve.

In the economic sections, the marginal relations describing cost-minimizing and profit-maximizing behavior are derived, both for the perfect competitor and for the monopolist. These are discussed in considerable detail. The case of a nondifferentiable production function is treated separately, but in fact the treatment is restricted to the case where all smooth parts of the production frontier but one are parallel to coordinate planes. Other cases are dismissed, surprisingly, as exceptional (p. 250).

The concluding chapters deal with depreciation and what the author calls reinvestment—the process of continual replacement to keep the size and com-

position of the capital stock constant. It is odd to find depreciation treated without any mention of interest rates. Since the rate of depreciation of a capital good is the rate at which its value is falling, it surely cannot be evaluated unless one knows interest rates now and in the future (or the market tells us the second-hand prices without our having to do any calculations). I am afraid that the student might be misled by Frisch's treatment, especially when he adds together the rates of capital service available from a given capital population in *different* years. It would be an unusual producer who regarded output in each of two years indifferently.

Finally, we must ask: does Frisch vindicate his claim that the traditional way of doing production theory, with a great deal of complicated differentiation, is the fundamental way, or the best way? I am not persuaded. It might be claimed that the presumably important case of U-shaped costs cannot be dealt with by the linear theory of production. Yet, although no treatment seems to have been published, it is quite easy to see how it would go; and the convenient language of concavity and convexity, of production sets and supporting hyperplanes, would provide a more direct route to the useful conclusions. It is, I think, one of the advantages of the modern theory that it forces one to consider what results one wants and for what purpose. We do not want systems of equations for their own sake. We want to know how a firm could calculate its best policy from the kind of data it actually has available; and we want to formulate results about the way in which output supplies and input demands depend upon the economic environment of the producer. There are really rather few results of the latter kind in the traditional production theory: the more special ones are conveniently derived by calculus, but the important general ones are usually more readily—and more generally—proved by the modern theory. As for computation of actual production policies, the methods of programming have proved much more powerful.

Yet the traditional theory of production is an impressive edifice, and Professor Frisch has given an impressive account of its fundamentals.

JAMES A. MIRRELEES

Trinity College, Cambridge

The Theory of Profit. By D. M. LAMBERTON. Oxford: Basil Blackwell, 1965. Pp. vii, 211. 37s. 6d.

This closely written book may be viewed as a study of the theory of the firm, rather than of *the* theory of profit, for the author is concerned with "the firm's major areas of decision, pricing and investment, in an attempt to establish the relationship between the nature of the firm and profit" (p. 7).

The point of view is disclosed in the preface:

The organizational model of the firm which I have suggested raises serious issues for current controversy about the theory of the firm itself. I believe that future development should be away from the traditional static, welfare-oriented approach to business behaviour and toward a theory of disequilibrium behaviour of the business firm.

There is much merit in this position, or in the view that "economists have

begun to show a rudimentary awareness of the importance of organization and information but hitherto there has been no attempt to probe the significance of these resources of the firm for the theory of profit" (p. 16). Many "orthodox" economists since Marshall would probably have accepted this proposition. Still, Lamberton may be right in his emphasis.

Along with competent surveys of the state of profit theory, Lamberton offers an interesting analogy between organizational change and technological change, as well as the effect of uncertainty on a theory of profit maximization. While these ideas, too, are not novel, Lamberton seeks to weave them into a more inclusive theory.

More dubious are propositions to the effect that "a management team will be more proficient the longer it has been a going unit" (p. 35), or that, rather than speak of the firm or the entrepreneur, we adopt the view that "in particular emphasis is [to be] placed upon organization and information" (p. 41). That this becomes distressingly vague is shown by his argument that:

But in all this activity it is the organization that is important. The emphasis should be shifted from the elusive entrepreneur to the firm, and to the study of the firm's perceptive capacity, communication system, and response mechanism. For the time being it seems wise to seek only a theory of decision-making . . . (p. 35).

I suspect that we shall still find ourselves talking of firms—as Lamberton does—and of entrepreneurs or entrepreneurial groups. To be sure, they may now become "managerial teams." Maybe the new name is better. But it is not a new *idea*.

Profit maximization, satisfactory profits, and sales maximization are considered as among the firm's objectives. While empirical studies are cited, the analysis of this part is inevitably inconclusive (Ch. 4). The chapter on "The Investment Decision," which considers marginal efficiency of capital and accelerator notions, will be useful as a guide to the literature, tying together some of the macroeconomic studies to the theory of the firm. In an era of multiproduct firms Lamberton does well to remind us that "details of profit on a product, rather than a firm, basis need to be known" (p. 145).

The final portion of the book is devoted to an interpretation of profit statistics as given us by the accountant; much of the problem comes in extracting imputed interest, rent, and excessive managerial salaries out of the totals—if we are ever clear on what "profit" really is. A chapter is devoted to the relations of market position, pricing, and investment. Much more work is needed on this set of topics for they contain little short of the workings of the enterprise economy.

While it is possible to conclude that Lamberton's own views on the theory of profit are not communicated with the clarity he intends, this is a stimulating book on the central concept of the capitalistic economy. Many incisive ideas can be derived from it and pursued in greater detail. Having sensed the elusiveness of the subject, Lamberton should be well prepared for a more definitive statement of his views.

It is a pity that recent studies of macroeconomic determinants of profit mag-

nitudes are omitted; these may be very important in revealing the operations of the enterprise economy; they deserve interpretation at the level of the firm. Empirical evidence on the near-constancy of factor shares also begs for evaluation in terms of the theory of the firm.

SIDNEY WEINTRAUB

University of Pennsylvania

On Competition in Economic Theory. By P. W. S. ANDREWS. London: Macmillan; New York: St. Martin's Press, 1965. Pp. ix, 141. \$3.25.

Mr. Andrews criticizes received static micro theory on numerous scores and feels that "economics will have to take a good hard look at its methodology and where it has been getting." He is in search of "a framework for further work on individual industries of a truly analytical kind, in which relevant factors in the internal structure of the firm would be linked with the analysis of the external circumstances in the industry." He is highly concerned about the "apparent victory of the theory of the firm" at the expense of a theory of industrial structure. He is critical, too, of the assumed falling demand curves of the firm with their "implicit theorizing," the treatment of selling costs and advertising which assume consumer irrationality, the analytical independence of cost and demand functions which marginal equilibrium theorists take for granted, and other aspects of micro-equilibrium analysis.

The framework and elements of Andrews' own approach are intermingled with his review and criticisms of static micro theory. Interpreting freely, the following preconceptions and elements seem to be basic for Andrews:

1. Consumers and buyers are assumed as "rational;" consequently, products and product differentiation are assumed as "real," and advertising and selling are assumed to be basically "informational," not merely wastefully persuasive.
2. Oligopolies and oligopolistic interdependencies are generalized throughout the economy; the collusive solution of some economists in received theory is rejected, however.
3. He has high confidence in "open competition" defined in terms of the entry of new competition both within given established industries and cross-entry from *other established* industries.
4. The "ring fence" about oligopoly within which economists play their games is removed by actual and potential open competition. Thus, the special connotations of oligopoly in equilibrium theory disappear; short-run disequilibrium must be analyzed in terms of industrial structure.
5. The demand curves facing the individual enterprise are not derived directly from consumer demand but from the supply prices of actual or potential competing suppliers.
6. A case-by-case approach is necessary in terms of the important particular variables and structural relations even though it may obscure the niceties of full price-output equilibrium in favor of a looser conceptualization of short-run equilibrium or balance with environment.

This reviewer is in agreement with most of Andrews' criticisms of static

micro theory, and with much of his own positive approach. Structural analysis in the setting of the environment of the enterprise is both reasonable and necessary. It would have been helpful, however, if Andrews had been more explicit as to the character and requirements of his own industrial structure approach. Does he have in mind the market structure approach of the so-called field of "Industrial Organization" in the United States? There is a notable lack of reference to this U.S. literature. There are references to some of the contributors, but only in terms of Andrews' own writing—as Bain on entry. Chamberlin appears and reappears throughout the volume, but not as a precursor of market structure theory but to the contrary.

One of the most interesting and, perhaps, revealing aspects of Andrews' stimulating suggestions and approach are his conclusions supporting resale price maintenance. He stands among a relatively small minority of economists in his position. Perhaps, the reasons for his favorable view may provide the key as to the specific nature of his own approach. His endorsement of resale price maintenance, insofar as I could determine, stems largely from his view that (1) small and medium sized manufacturers often can and should be maintained among actual and potential competitors, and (2) such survival and continuation requires the presence of specialized dealers offering valuable pre-sale services (as in the book trade) that would be lost or weakened in competition with large, diversified, limited service enterprises using price-leader tactics. Andrews uses the Net Book Agreement in England to illustrate how received static micro theory based on Chamberlinian large group ("monopolistic competition") analysis has led the majority of economists into allegedly unsound recommendations with respect to public policy.

Now, Andrews' approach in terms of the impact of open competition, especially cross-entry in competition, and the difficulties, if not impossibility, of establishing cost functions for individual products in retail competition, could lead to just the reverse conclusion when couched in terms of competitive functioning under given market structures. Andrews' own judgment and recommendations would appear to reflect a social judgment as to the public benefits derived from encouraging and maintaining a larger number of small and medium sized producers and of specialized retailers than might occur if resale price maintenance were prohibited.

In essence, it would appear that the lack of sharper positive formulation in Andrews stems from a relative overemphasis upon the particular industrial facts and of judgments of public benefits in contrast with a framework in terms of competitive generalization. Along these lines it is extremely difficult for the most determined, objective scholar to avoid the pitfalls of rationalizing the business *status quo*. The formulation of a general theory would appear to require that the approach be oriented first from a framework of generalization about competitive functioning, modified then in each case by special factors, rather than the reverse.

Capital Longevity and Economic Growth—An Analytical Study. By S. K. BHATTACHARYA. Calcutta: Bookland Private Ltd., 1965. Pp. vi, 146. Rs. 20.

The book under review is, with minor changes, the author's thesis for the Ph.D. degree at the University of London. The study sets itself the task of putting "the relationship between capital longevity and economic growth on a more integrated and realistic basis than has been the case so far." This is an interesting and important problem since theoretical studies of optimal life of capital equipment have usually been carried out at the micro level, while the corresponding problem has been given a rather superficial treatment in macro-economic growth models.

As preparatory work the author surveys some of the microeconomics of capital longevity (the term used for economic lifetime, in contrast to "durability," which is used for physical lifetime). He criticizes earlier approaches for neglecting variations in operating costs—or rather the relationship between variations in repair and maintenance expenses and the output capacity of equipment. The author's attempt to remedy this is suggestive, but a precise and convincing theory is not presented. Then follows an attempt to include the impact of technical progress. There is no doubt that the author comes out with the correct general conclusions, but the analysis is a little bit obscure because of an unjustified use of "the law of indifference in the market." The missing link in the analysis is some explicit assumptions about foresight or expectations.

The macroeconomic analysis is opened by a survey of growth models which deal explicitly with technical progress and depreciation in some form or other, covering models by Solow, Domar, Haavelmo, Strumilin, and the present reviewer. Many recent extensions of these models (by Massell, Kurz, Phelps, Kemp, Thanh, and others) ought to have been included, but were probably not available when the thesis was written. The survey is competent as far as it goes, emphasizing the aspects of the models that are most relevant for the author's problem, but one might wish for more careful economic explanation of some points. For instance, in connection with a growth model by the present reviewer in which gross investment is assumed to be a constant fraction of gross income, the author comments on the dependence of the growth path upon the rate of depreciation (or average lifetime of equipment) without discussing to what extent this dependence is due to the effects of the rate of depreciation on the net investment ratio. The more original section of this chapter is an attempt to interpret Strumilin's analysis of "The Time Factor in Capital Investment Projects."

In his survey the author finds that the savings ratio and the rate of depreciation affect the asymptotic growth rate in some models, while they do not so in others. He shows how this is related to the form of the production function. Furthermore he discusses why there will in some models, but not in others, exist an optimization problem with respect to capital lifetime. This discussion is well taken. He goes on to extend some of the models by introducing a spe-

cial cost function for the manufacturing of capital equipment of different durabilities. This, of course, tends to create more of an optimization problem with respect to capital lifetime.

Finally—in the most original chapter—the author introduces a hypothesis according to which there is a trade-off between initial investment costs and later repair and maintenance costs. The implications are discussed both at the micro and macro level. The macro model is an adaptation of the reviewer's growth model (*Econometrica* 1959) in which there is a choice-of-technique-function with substitution between labor and capital at the stage of designing equipment, while factor proportions are "frozen" after the equipment is installed. It appears that the asymptotic growth rate is independent of the choice of the ratio between investment costs and repair and maintenance costs, and also of the "rate of retirement." However, in both these respects there is scope for optimization as regards the *level* of the asymptotic growth path. This optimization is convincingly carried out, and some interesting conclusions are obtained. I should, however, like Bhattacharyya to extend his analysis further, viz., to make an attempt to "translate" his formulae at the macro level back to the micro level so as to see if some natural and comprehensible rules of decisions with respect to retirement and repair and maintenance vs. initial investment costs at the micro level could be given so as to conform with his macro optimization. Furthermore, one might wish for an analysis which would not concentrate only on the asymptotic results.

Most of the mathematics is presented in appendices. At least on one occasion (p. 99-100) the author complicates things unnecessarily, but on the whole the analyses appear competent and reliable.

The Currency and Financial System of Mainland China. By TADAO MIYASHITA. Tokyo: The Institute of Asian Economic Affairs, 1966. Pp. viii, 278. \$7.50.

From 1911, when the Manchu dynasty fell, to 1927, when Chiang Kai-shek's Nationalist government came to power, China had no strong central government to mend its political disunity. And even Chiang's regime, beset as

it was by the Japanese invasion, frequent battles with local warlords, and continuing struggles against the Chinese communists, was far from a completely unifying force. Nevertheless, despite the turmoil, there *was* industrial growth in China from 1911 on, but it was located mostly in the treaty ports and in Manchuria (which was developed largely by the Japanese after their occupation in 1931). Industrial growth was confined to small areas and hardly touched the masses of Chinese; it was a thin foreign ring around the edges of one of the world's poorest and most miserable countries. For China proper there was little or no economic development in the 1930's and 1940's, but there was an abundance of inflation.

Arthur N. Young, who was financial adviser to the Nationalist government from 1929 to 1947, has written an "insider's" account of his and others' futile attempts to halt China's inflation, which commenced shortly after the start of all-out war with Japan in 1937 and lasted through the final curtain in 1949.

The inflation got under way "slowly" in 1938 when prices rose by about 3 per cent each month. The average monthly rate climbed to 5 per cent in the following year and then to 7 per cent in 1940. From mid-1941 to late 1944, prices rose by 10 per cent per month; and by 20 per cent from then to the war's end in 1945. Although Young carries the story only to this point, he does note that, from August 1945 to late summer 1948, prices rose 2500 times, equal to their climb during the previous eight years. And, in the final months before the total collapse and the flight of Chiang to Formosa, the price index also took off and disappeared into the great beyond.

The immediate causes of the inflation, according to Young, were the vast increases in government expenditures and the grossly inadequate tax system. While government spending in current prices about doubled each year from 1937 to 1941, then tripled annually to 1944, and finally jumped fivefold in 1945, in real terms these expenditures actually declined by 30-40 per cent over the period. The tax system, however, simply could not respond adequately to large increases in nominal incomes and spendings. In current prices, budget receipts lagged farther and farther behind expenditures; and, in real terms, they fell by perhaps 75 per cent from 1937 to 1945. The weakness of the revenue system was due not only to the antiquated tax structure itself and to disorganization caused by fighting, but it also reflected the conflict of class interests and the corruption within the Kuomintang's own ranks. Although Young is sympathetic to the Chiang regime, many passages in his book are devoted to the abuses, bribery, thefts, and extravagances of some of its officials and leaders.

Young points out that the ever-expanding budget deficits were almost entirely financed by the creation of money—mainly by new issues of currency. Consequently, nominal money rose sharply after 1937, but it did not keep up with the steep ascent of prices: real money balances fell by more than 80 per cent during the period, reflecting a massive flight from money.

In the face of these powerful inflationary forces, the efforts of Young and others to slow down the price rises were woefully ineffective. The government tried bond sales to the public and later gold sales, price controls, foreign

exchange stabilization, control of interest rates; it received lend-lease, gifts, guarantees, currency backing—all to almost no avail. Young's book, unfortunately, deals mostly with these futilities and very little with the basic difficulties. The first part of the book sets out the facts regarding budget expenditures and receipts. Part two contains a discussion of the extent to which budget deficits were covered by borrowing from the public, borrowing abroad, and foreign aid. The third and longest part takes up the government's attempts to check the inflation by various monetary policies, exchange stabilization schemes, and price controls; and this part ends with an analysis of the causes and effects of the inflation.

For much of his economic analysis, Young draws on two earlier studies of the inflation,¹ one of which, in this regard, is superior to his own work, but both of which tell essentially the same story that he does—not surprisingly, because the Chinese inflation was “classic” in virtually every way. Young concludes that the inflation was primarily due to excessive creation of money, that overall scarcity of goods was not an important element in the price spiral (the contrary view was held widely at the time in Washington), that among the heaviest losers were army personnel and civil servants, and that inflation, as usual, led to corruption and inefficiencies.

The book is particularly interesting in its accounts of the author's battles with Washington over policy measures for China. In one of these accounts, he accuses the U.S. Treasury—Harry Dexter White in particular—of “foot-dragging” during the period when the United States was sending gold to the Nationalist government so that it could be sold to the public in exchange for excess money balances. “The deliberate foot-dragging and obstruction of needed [gold] shipments, despite China's urgent pleas, was primarily the work of White and other subordinates . . .” and “White's efforts in 1944-1945, while blocking gold shipments to China, to promote a US \$10 billion postwar loan to Russia, show a strong anti-Chinese and pro-Russian bias” (pp. 296-97, 298).

The two books footnoted above continue the story after Young leaves it: to the resumption of inflation, the monetary reform of August 1948, another in July 1949, and the denouement. Young, in glancing at these later years, concludes that the inflation was a major cause of the Communist victory and that those (in Washington) who aggravated the inflation “must bear part of the responsibility for later tragic events” (p. 298). Aside from other dubious implications of this statement, the implied efficacy of gold sales in China as an anti-inflationary device seems grossly exaggerated.

The hyperinflation was finally halted by the Communists by mid-1950, which cleared the road for economic reconstruction and development. As it turned out, Communist China had one of the fastest-growing economies in the world during the 1950's. Her annual rate of output growth was probably around 9 per cent, though this figure was influenced by the depressed levels of economic activity at the beginning of the decade and by the frenzied output drives of the Great Leap Forward at the end. A succession of disastrous har-

¹ Kia-ngau Cheng, *The Inflationary Spiral: The Experience in China, 1939-1950*, New York 1958; Shun-hsin Chou, *The Chinese Inflation, 1937-1949*, New York 1963.

vests starting in 1959, disincentives growing out of life in the communes, inefficiencies from the Great Leap, and the pull-out of almost all Soviet technicians in mid-1960, at first slowed output growth and finally tilted the economy downward. Output may or may not have fallen a bit in 1960, but it almost certainly declined, perhaps substantially, in the following year. Since 1962 or 1963, there has been a resumption of growth but at a rate below that of the 1950's.

The spectacular gains of the 1950's were based in large part on an ambitious investment program, especially in the industrial sector. Gross domestic investment averaged more than 25 per cent of gross output, and it was probably at least 30 per cent if investment in human capital is included. At least half of this figure was capital formation in heavy and light industry. For one of the world's poorest countries, in terms of income per capita, this was a most remarkable achievement.

The relatively large investment expenditures in the industrial and transportation sectors, which grew especially fast in the early years of the decade, created strong inflationary pressures for consumer goods and services, and particularly for food products. Since very little investment went into agriculture, the State attempted to increase agricultural output by social and political reorganizations that were intended to raise incentives and efficiency. Land reforms, mutual-aid teams, elementary and advanced agricultural cooperatives, and communes were the principal innovations along these lines. They were of some success, but in the end they were pushed too far and too fast. Since 1961, the State has played down reorganizational features and has stepped up agricultural investment expenditures.

These were the attempted solutions on the supply side. On the demand side, the heavy investment program required restraint of demand for consumption, or, what is the same thing, sufficient saving to match the investment. The Communists, having just witnessed the devastation in the wake of the hyperinflation on which they rode to power, were determined not to gain the required saving through an inflationary process. Instead, they greatly increased tax receipts and held down government consumption, thereby generating saving in the government sector; they used direct controls and manipulated relative prices to achieve large profits in state enterprises, most of which reverted to the budget and so swelled government saving; they encouraged individual saving by creating attractive financial assets with purchasing-power clauses, lottery features, etc., and by establishing thousands of new banking offices around the country; and, finally, for a time they were able to tap some foreign saving for their investment program. Although the supply of consumer goods did not expand vigorously after 1953, demand was restrained sufficiently to prevent any significant increase in prices.

The study by Dwight Perkins, *Market Control and Planning in Communist China*, covers much of this story, but the material is so poorly organized that the reader is continually struggling to put the various pieces together. It is hard to tell what the basic trouble is, but it may be that the book is organized around sectors and markets—agriculture, industry, labor, consumer goods—

which leads to just as many partial views of the economy, preventing the reader from ever seeing the whole picture.

Perkins apparently pursues two problems. The first is a stabilization-growth problem, as expressed in my paragraphs above: given the huge investment program, how could the required saving with fairly stable prices be obtained? The second concerns resource allocation: what role did "the market" play in allocating resources and goods? While the analysis of the second problem at times is served fairly well by the sector-by-sector approach, the discussion of the first, to which I now turn, decidedly is not.

Perkins shows that the Communists successfully rejected inflation (and forced saving) as a method of financing their investment expenditures. The official retail price indexes record an annual increase of only one per cent from 1951 to 1958, and there are no indications of a prolonged serious inflation after that. These indexes, though, probably have a downward bias, as Perkins explains, since they are based largely on controlled prices which were at times below equilibrium levels. Black-market prices apparently exceeded official prices in 1953, 1956, and 1960-62. However, as Perkins states: "None of these qualifications . . . negates the basic contention that price increases in Communist China have in fact been quite modest" (p. 158). The potential excess demand was largely eliminated by other means.

Perkins describes well the State's attempts to raise agricultural output. Land reform, while primarily a redistribution measure and a means of destroying the landlords, was meant to increase incentives toward land improvement. The regime also used advance-purchase contracts containing state-guaranteed purchase prices, eliminating some of the risks to individual farmers. Later, in November 1953, the State began to use compulsory quotas for major crops, principally for the purpose of controlling the marketed portions of the crops. In 1955-56, peasants were organized in agricultural producers' cooperatives, in which income was distributed on the basis of the amounts of labor and land contributed; later, in the advanced cooperatives, only the labor contribution counted. In the summer of 1958, communes were established, which expanded the basic unit from around a few hundred families to several thousand. The communes were subsequently reorganized: the center of control was located in lower-level units and peasants were encouraged to devote some of their time to small private plots. Finally, the government has in recent years stepped up its investment spending in agriculture.²

The author feels that land reforms, while raising peasant incentives, removed many rich peasants "who had more capital and better knowledge of advanced techniques of farming than poor peasants"; that centralization in the form of cooperatives and communes was mostly a failure. He concludes that "there appears to be little that centralization accomplishes that cannot be done better through extension services, taxes, and market and price controls in the context of a free peasant economy" (p. 97).

The lack of success on the supply side made it that much more urgent for

² A stimulating analysis of these events is found in Franz Schurmann, *Ideology and Organization in Communist China*, Berkeley 1966, ch. 7.

the government to restrain demand for consumer goods and services. The required saving came in large part from tax receipts and profits of state enterprises, very little from foreign saving. Perkins believes that individual saving did not contribute much, that the drives to elicit such saving were "makeshift measures," that they had a "negative effect on incentives [which outweighed] their usefulness in controlling inflation or in accomplishing other objectives" (p. 176). In my judgment, some of this is correct and some is wrong, but in no instance does the author offer adequate support for his contention.

For example, while government saving through the State budget grew remarkably from 1950 to 1960, owing to rapid growth of budget revenues relative to government consumption and transfer payments, Perkins shows only the budget revenue figures. Further, they are not related to anything at all—to investment, GNP, etc. In fact, there are no GNP figures in the entire book, and yet good estimates exist; worse yet, despite the fact that the investment program is so vital a part of Perkins' story, nowhere does he present aggregate investment data—and they, too, exist.⁸ Consequently, it is not possible for the reader to judge how important budget receipts were in financing the total investment program.

In fact, budget revenues rose from around 10 per cent of gross product in 1950 to over 30 per cent in 1958 and even higher in the following year; government saving probably financed about half of aggregate investment in the early years and more than three-quarters later on. Perkins' description of the tax system that largely produced this impressive record is fragmented, but it is clearly shown that the most rapidly growing revenue source was from the profits of state enterprises. Large revenues in the earlier years, according to the author, were also provided by taxes on the net income and gross receipts of business firms and by commodity taxes. All of these were replaced in 1958 by the turnover tax. The agricultural tax, which was imposed on the gross yield of output and the base of which was "normal" rather than actual yield, declined steadily throughout the period relative to total revenues. In 1950 agricultural tax revenues were about one-third of budget revenues but only 5 per cent in 1960.

With regard to individual saving, Perkins' views are unsupported. He emphasizes the unimportance of this saving, and yet his figures show fairly sizable increases in deposits and bond holdings, although, once again, they are not related to anything. Apparently because he feels (correctly) that coercion was used in the savings drives, he is quick to ascribe large disincentive effects (work?) to the resulting saving. He offers no evidence for this except to say that such saving would be akin to a tax—an observation that raises more questions than it answers.

In fact, there must have been very large increases in the real demand for financial assets during the early years of development—not only for the sav-

⁸ See Alexander Eckstein, *The National Income of Communist China*, New York 1961; William Hollister, *China's Gross National Product and Social Accounts, 1950-1957*, Glencoe, Illinois 1958; T. C. Liu and K. C. Yeh, *The Economy of the Chinese Mainland*, Princeton 1965; and C. M. Li, *Economic Development of Communist China*, Berkeley 1959.

ings deposits and bonds discussed by Perkins but also for money balances and other financial assets. For one thing, the cessation of hyperinflation would in itself renew real demands for financial assets; and the rapid increase in national income would add to them. Further, several key financial assets were provided with purchasing-power clauses or lottery features; mobile banks were sent to rural areas; new types of savings deposits were introduced; new financial institutions were established; saving through insurance contracts was vigorously pushed. Moreover, the land reforms, by decentralizing ownership and decision-making, probably raised both the demand for and the supply of loanable funds in the rural areas, as many poor and middle peasants, owning land for the first time, had to finance expenditures, and many acquired saving for the first time from sales of grain to the State. In addition, demand for money was probably raised by the increasing efficiency of the payments mechanism: the early consolidations of currency issues, establishment of clearing houses, the reduction of remittance charges. Finally, there were forced saving schemes and patriotic savings drives.

These factors, combining their forces in the early years of the period, must have raised real demands for financial assets far above the growth of income. But it is likely that later on, as the economy was socialized—private businesses eliminated, cooperatives and communes established—the real demand for financial assets lagged behind the growth of national income. This is suggested by some preliminary estimates I have made, which show non-State net domestic saving growing very rapidly from negative amounts in 1950-51 to about 4-5 per cent of NDP in 1953-55, and after that declining. These estimates would mean that such saving financed a negative part of total net investment in the initial years, 15 to 20 per cent of it by 1953-55, and probably a declining portion thereafter.

Perkins' second theme, as I have said, is on the role of the market in resource allocation. He shows that market forces were much more significant in agriculture than in industrial production and construction; in the former, the authorities used varying purchase prices in the early years to influence outputs of certain crops, and, even with the advent of cooperatives, "a free market was still the major determinant of a wide range of subsidiary products" (p. 199); in the latter, the major allocating device was the physical plan targets. Perkins finds that the market played a leading role in the distribution of consumers' goods, but that there was a high degree of physical control over the labor market. He concludes that the market has played "an important role in directing the Chinese economy, but a role subordinate to that of centrally determined physical controls" (p. 200), an assessment that seems obvious and correct.

A thesis which is expressed several times in the book is that central planning may be easier in an underdeveloped economy like China's than in a more developed economy, because of the smaller number of commodities produced, the simpler interdependencies in the production and allocation of these commodities, a relatively simple labor market, and China's ability to borrow technology from highly developed nations (which obviates the need to stimulate technical advance through market forces). However, he also sees impor-

tant drawbacks to centralized controls in China, among them the lack of adequate data, insufficient numbers of trained people, the sheer size of the country, and the large number and diversity of farms. While the pros and cons are mostly left hanging in the air, Perkins seems to feel that the net advantage lies with the market. Still, as he points out, these economic considerations were unimportant in China's decision to impose central planning; much more significant, of course, were ideological and political factors.

The material is poorly organized for a book, the discussion of banking is very bad, some of the tables present nothing but puzzles and mysteries, and the most important data are missing. It is to Perkins' credit, however, that despite these flaws, he has so many interesting things to say that his book is well worth reading.

Alexander Eckstein's study on *Communist China's Economic Growth and Foreign Trade* examines the extent to which China was able to further her investment program (and so her economic development) through international trade, loans, and aid. While he does not examine the role of government and individual saving, he concludes that China's growth would have been markedly reduced without foreign help. This conclusion, however, does not rest on the magnitude of China's foreign trade (on trade benefiting both sides), for her imports were probably no more than 4-5 per cent of her gross domestic product, but rather on other considerations.

It is generally felt that foreign trade may allow a country to increase its domestic investment in two principal ways. First, if foreign saving is available the resulting import surplus releases real resources, at a given consumption level, for investment purposes. Second, even if foreign saving is not tapped (i.e., imports equal exports), a country's domestic investment might still be enlarged if it has net imports of investment goods. Suppose a country imports investment goods and exports an equivalent amount of consumption goods. Then its domestic investment is higher to the extent that it could not have produced the investment goods at home with the real resources that went into the exported consumption goods.

Eckstein's conclusion, therefore, rests on an examination of these two matters; and I shall consider each in turn. To what extent did China have access to foreign saving? As Eckstein shows, while the answer to this question is uncertain, it is probable that China had on balance little or no import surplus during the period 1952-63—and this would also be true for the longer period of 1950-65. The answer is uncertain because China's imports and exports can be built up best from the trade data of the countries trading with her; and thus, the data are in terms of foreign currencies. This means that the yuan amounts of imports and exports can be obtained only by converting the dollar, ruble, etc. figures into yuan at an appropriate exchange rate. Ideally, one would want to value China's exports at the yuan prices that reflect the worth of real resources going into producing them; and to value her imports in yuan prices that reflect the worth of real resources that would have been used to produce them domestically.

It is generally agreed that in China prices of investment goods were "high" while prices of consumption goods were "low." China's exports, then, consist

ng mostly of consumption goods, would be overvalued in yuan if the official exchange rate were used to convert dollars to yuan. That is, if China exported one dollar of consumption goods at world prices, the official rate would yield a yuan value in excess of the actual value in China's economy. Similarly, imports would be undervalued because they consisted largely of investment goods (up to 1960), the prices of which were relatively high in China. Consequently, if a rate of 2 yuan = 1 dollar is used for exports, a rate of, say, 3 yuan = 1 dollar should be used for imports.

Inasmuch as no-one knows the "correct" rates, Eckstein begins by using the uniform (official) rate of 2.62 yuan = 1 dollar for both imports and exports.⁴ His calculations reveal an *export* surplus of 4.1 billion yuan for 1952-63, which, if correct, means that on balance China was an exporter of capital. However, the export surplus is small, amounting to less than $\frac{1}{2}$ of 1 per cent of cumulated GNP for these years.

Eckstein shows that China had import surpluses up to 1955 and export surpluses thereafter. This was her trade pattern over time with other communist countries, in particular with the USSR; the opposite pattern, however, prevailed with noncommunist countries. Her early overall import surpluses were financed by credits (loans, not grants!) from the USSR, and her later export surpluses were used to repay the USSR loans and to extend aid to other countries. Up to the present, China has probably extended more foreign aid than she has received (but not all of her aid has been drawn upon); moreover, her terms have been more generous than those extended to her—she has made outright grants (and probably received none), has given longer maturities, and some of her loans have been interest free.

Thus, according to these data, China did not tap foreign saving over the period as a whole; instead, on balance, she may have exported capital to other developing nations. She has financed her investment program from her own saving, and has used a (small) part of this saving to aid other countries.⁵

However, some studies have suggested that exchange rates other than the official one should be used in computing China's exports and imports in yuan. As Eckstein explains, one study suggests a rate for the export of consumer goods of 1.79 yuan = 1 dollar; another points to a rate for the import of capital goods of 5.91 yuan = 1 dollar. While Eckstein has serious reservations about these rates, he uses them and obtains a substantial import surplus for China during 1952-63, which is equal to 5-6 per cent of her cumulated gross domestic product. In my judgment—and, I believe, in Eckstein's, too—this is clearly too high. For one thing, imports were by no means all capital goods, especially after 1960 when one-third of imports was foodstuffs; and not all exports were consumer goods. More important, such a high import surplus figure is grossly inconsistent with "companion" data on domestic investment, government saving, and what we know about private (non-State) saving. China may

⁴ This has been the official rate since mid-1957, when it was indicated that the previous rate of 2.36 = 1 overvalued the yuan.

⁵ It should be noted that, although Eckstein does not say so, his data include only commodity trade and not services. However, a recent unpublished study by F. H. Mah, which includes both, shows about the same picture.

have had an import surplus during the period, but it is unlikely that it was very large. And so it is unlikely that China's development was financed to any significant extent by foreign saving for the period as a whole.

Turning now to the second question, to what extent did China further her economic development by importing capital goods? Again, one cannot be certain about the answer, but it is fairly clear that China imported capital equipment, chemicals, and metals in heavy volume up to 1960, including complete plants from the USSR with technicians and advisers; but then mostly food products from 1961 on. She exported some investment goods—to North Korea, North Vietnam, and other countries—but mainly food products and textiles, especially the latter after 1960. Data in Eckstein's study and elsewhere suggest that China's net imports of investment goods amounted to 10-15 billion yuan for the years 1952-63, or to about 3-5 per cent of her total domestic investment.

Eckstein, going after the problem differently (because the above estimates come from some rather shaky figures), computes the extent to which net fixed-capital investment would have fallen if China had not imported machinery and equipment (a component of fixed-capital investment). This estimated decline, for the period 1952-56, is about 10 billion yuan—that is, from approximately 43 billion yuan to 33 billion yuan. The higher (or actual) figure was associated with a 27 billion yuan increase in net national product; so the lower figure, it is assumed, would have yielded an increase in net output of 20 billion yuan—which is 7 billion below the actual increment. For the period 1953-57, this signifies a reduction in the annual growth rate from 6.3 per cent to something less than 5 per cent.

It should be noted that these calculations apply to the 1953-57 period, when net imports of machinery and equipment were at their peak. Moreover, Eckstein assumes that the ratio of equipment investment to total fixed-capital investment is constant (40 per cent); hence, a decline in the numerator, owing to a decrease in imports, would reduce the denominator by a multiple of the decline in equipment investment. If one assumed, instead, that the other components of fixed-capital investment would not be affected by the reduction in equipment imports, the importance of the imports would of course be much less. Also, Eckstein assumes that, if equipment imports decline, capital goods could not be domestically produced with the real resources released from the counterpart exports. To the extent that such substitution could occur, the output growth rate would be less affected by a decline in imports. On the other hand, the actual yuan value of machinery and equipment imports may have been higher than the level suggested by the exchange rate of $2.62 = 1$. If so, the elimination of those larger imports, everything else the same, would have a larger impact on the output growth rate.

So the matter is pretty much up in the air. But there is little doubt that, at least up to 1957, China's growth rate was boosted by her import surpluses and by the large capital-equipment component of these imports. Thereafter, and especially after 1960, her growth rate probably suffered, as she ran export surpluses to repay debts and to extend aid to other countries, and as her own capital-goods exports probably surpassed her import of such goods. So it is

quite likely that the higher growth rates in the earlier years and the lower ones in the later years were significantly influenced by foreign trade and aid factors.

Eckstein has more in his book than that. His beginning chapters on China's economic development and the pre-conditions for it are highly informative and analytically pleasing. And, at the other end of the book, there is much worthwhile detail regarding China's trade with individual countries, both communist and noncommunist. Eckstein's study is an important one.

Since Perkins has some material on government saving—the tax structure and the system of direct controls as a device for raising profits of state enterprises—and since Eckstein takes up foreign saving and trade, it would have been nice if Tadao Miyashita had completed the job by analyzing the role of the financial system in eliciting individual saving. But, while his book on *The Currency and Financial System of Mainland China* provides some information on this question—though really little more than Perkins gives us—its strengths lie elsewhere: in descriptions of the Communist financial structure and of the problems it has faced in the past two decades.

Miyashita gives a rather complete picture of the financial system in China, including street addresses for some of the financial institutions and photographs of the new currency issues and of the head office of the People's Bank of China—the central bank. When Arthur Young was financial adviser to the Kuomintang, there were four main government banks, a few dozen, highly influential foreign banks, some modern Chinese banks, and several hundred so-called native banks. One of the government banks was the Central Bank of China (organized in 1928), but it never did attain the status suggested by its name; there was no strong monetary control during this period. Chinese banking was heavily concentrated in Shanghai, and only rudimentary credit and saving facilities existed in rural areas where most of the people lived.

When the Communists came to power, the Central Bank of China was replaced by the People's Bank, which issued all of the currency and conducted ordinary banking business, making most of the short-term loans and having large deposit liabilities to nonfinancial units. Of the other three government banks under the Kuomintang, the Bank of China became a joint state-private institution specializing in foreign exchange and overseas Chinese remittances; the Bank of Communications attained the same status, specializing in loans for capital construction until October 1954, when this function was taken over by the newly established People's Construction Bank; and the functions of the Farmers Bank of China were assumed by rural credit cooperatives, the People's Bank itself, and the Agricultural Bank of China (reorganized in November 1963). Several other new financial institutions have been created, monetary controls highly centralized in the People's Bank, and credit and saving facilities greatly extended.

Miyashita presents an excellent, detailed account of the development of financial control. The distinctive feature of the system is the large number of special funds supplied to economic units, each of which can be used for only one purpose and no other. Budget funds differ from credit funds in that the former are grants to be used for investment and the latter are loans for oper-

ating expenses. The budget funds themselves are divided into subfunds according to use—water conservancy works funds, forestry funds, etc. Some funds paid out of the budget ("fixed sum liquid funds"), however, are for normal operating expenses, while "excess fixed sum liquid funds" are credit funds for exceptional, temporary current expenses. Since July 1961, 20 per cent of the fixed sum liquid funds have come from the People's Bank (by way of the budget) as short-term loans. There are also commodity funds and noncommodity funds and many other categories. In addition, the authorities have established currency control in which most payments are made by check through the People's Bank and currency holdings are tightly limited, any excess having to be deposited almost immediately.

The author devotes two chapters to the currency policies of the Communists in the areas they controlled before 1949; he discusses the problems connected with the State's unification of the dozens of currencies outstanding when the Communists came to power, the stopping of hyperinflation, the socialist transformation of private banking in Shanghai, and the development of the rural credit cooperatives.

All in all, the book is full of information but devoid of critical evaluation; except for a few miscellaneous numbers, the author is not interested in statistical material. He *is* interested, though, in treating his subject accurately—even going so far in this direction (as do Perkins and Eckstein) as to call the present capital by its correct name, Peking, instead of Peiping.

These books leave little doubt that the economy of the People's Republic of China (correct name, at last!) has been made over from top to bottom and back again. There have been bold experiments (some failures), good and bad luck, and a lot of turmoil, but beneath it all a substantial improvement in the quantity and quality of the country's human and nonhuman resources. While these studies understandably concentrate on the machines and buildings, China's dramatically successful efforts to raise the health, education, and welfare standards of her people would also seem to be worthy of attention. It apparently is true that our profession's "China experts," for some reason, have shied away from this topic.

Development and Economic Policy in the UAR (Egypt). By BENT HANSEN and G. A. MARZOUK. Amsterdam: North-Holland Publishing Company, 1965. Pp. xv, 332. \$9.80; 70s.

The purpose of this important book is to provide a strictly economic analysis of the profound socio-economic changes experienced by Egypt since the end of World War II. It is not intended to be "an encyclopedia on the Egyptian economy," and many interesting and "important special questions are superficially dealt with," indeed, some are "not even mentioned." The book is a series of analytical surveys "by economists for economists" of the "main economic trends, problems and policies" in postwar Egypt. Economic philosophies of the "Hegel-Marx-Rostow" type are eschewed and the stress is placed

on economic analysis based on "just ordinary modern economic theory" (p. xiii).

If "ordinary theory" means simply "non-mathematical," we agree with Hansen and Marzouk that there is, for instance, very little connection between Hansen's contribution to this book on development and policy and his highly analytical *Lectures in Economic Theory* (Cairo, 1964), given at the Egyptian Institute of National Planning presumably during the time this book was being written. Indeed, on some key subjects (e.g., pricing and efficiency, and inflation, the budget deficit, and the exchange rate) the distance between theory and its application is disconcerting to an economist, be he teacher or advisor. Yet, having read this book, one can agree with the authors' statement that despite its shortcomings ordinary modern economic theory does bring us a "long way towards a full understanding of the economic problems of developing countries" (p. xiv).

Essentially, Hansen and Marzouk have written a series of survey essays on various aspects and sectors of the Egyptian economy. After an initial bird's-eye view of the economy during the past fifty years, cast primarily in terms of national income and product aggregates,¹ each survey essay (one to two chapters in length), focuses on a major segment of the economy. They start, appropriately enough in the case of Egypt, with the population problem. They admit that Egypt is densely populated, its population highly concentrated along the Nile, its agricultural frontier long since closed (the completion of the High Dam at Aswan will not significantly alter this situation), and, the recent findings of Professor Abu-Lughod of Smith College² notwithstanding, that Egypt not only is overurbanized, but that it is increasingly becoming more so—the degree of urbanization, they say, has increased by a fourth since World War II. But having said this they conclude that most of the pessimism concerning Egypt's high rate of population growth (2.9 per cent since 1947) is unwarranted since the data of the 1950's (on which the rate is based) are misleading due to factors peculiar to that decade. For instance, they maintain that the rise in the fertility rate was due mainly to "speeded-up births," and therefore is temporary. They also note that there was a temporary increase in marriages at the very end of 1959 so that population projections based on the data of the 'fifties give too high a future growth rate. They thus feel that the optimism of the "transition population theory," wherein industrialization, urbanization, and improved education will ameliorate the population problem, best describes the eventual result of the income-population race in Egypt. Later they state that this process is already occurring, what with the average productivity of both land and labor increasing in agriculture. With real in-

¹ In a Statistical Appendix (pp. 317-25), which enhances the value of the book, are the results of the various Institute of National Planning *Memoranda* written by Hansen (and D. Mead) on the national income, outlay and savings of the UAR during the period 1939-1962/63.

² "Urbanization in Egypt: Present State and Future Prospects," *Econ. Develop. and Cull. Change*, Apr. 1965, 13 (3), 313-43. Her main point is that, in the future, "Overconcentration of the urban population in relatively few cities, rather than "over-urbanization" *per se*, appears more serious and likely to emerge as the key bottleneck in any program of industrialization."

comes of agricultural labor increasing by 15-20 per cent since 1950 they feel Egypt is far from "the Malthusian nightmares usually associated with the agricultural situation in underdeveloped countries."

There follow two essays on agriculture and industry. A chapter analyzing the structure of each sector is followed by one evaluating the government's policies in these areas. There is a wealth of information in these four chapters: we choose only the following for detailed comment. We are told that while there is considerable seasonal unemployment in agriculture "about 25 per cent of the total permanent labor force, calculated on an annual basis," nevertheless the oft-repeated assertion that much of Egypt's agricultural labor force is suffering from disguised unemployment with a marginal productivity of near zero is incorrect (pp. 61, 64, 161, 298). What is worse, much of the investment planning in Egypt has been based on this mistaken "standard assumption of surplus labor in agriculture." Although the Five Year Plan puts the number of required agricultural workers at 3.2 million while actual employment in 1960 was 4.2 million, Hansen and Marzouk say this does not necessarily imply disguised unemployment with near zero marginal productivity in agriculture. If anything, this indicates only the extent of seasonal unemployment³ and so does not justify a zero shadow price of labor which they maintain has been used by Egypt's planners.

According to their estimates the value of the marginal product (VMP) for agricultural labor is positive and roughly equal to the wage rate. As Hansen has more recently stated,⁴ "The Egyptian fellah is an economical and calculating peasant" who would not employ labor at a positive wage if the resultant increase in production was "near zero." Using data of the 1950's they demonstrate this equality between wages and the VMP. At that time the annual wage (for 300 days) approximated £E35. Output per laborer averaged between £E90 and £E110. Since the labor coefficient of the Cobb-Douglas production function for this period was 0.3 the VMP of labor "should be about one-third the average output," or some £E33. Thus, for the 1950's the VMP did approximate the annual wage. They add "the equality of wages and marginal value productivity holds true back to 1937, at least." So disguised unemployment is banished, as is Lewis' contention that industrial expansion can occur "with little or no increase at all in money wages," although Table 5-18 indicates money wages have been constant since 1956!

In any event disguised unemployment as a widespread phenomenon in Egypt reappears when the authors state "it is in the Government sector that disguised unemployment in Egypt is to be found" so that "if zero-productivity of actually employed labour is . . . anywhere in Egypt, it is most probably in Government administration." They also stress that, unlike the disguised unemployment in industry, which is but a temporary phenomenon of the government's "Great Employment Drive" of 1961—when the productivity of in-

³ Their analysis makes use of the 1950 Agricultural Census since the data for 1960 "has not yet been published" (p. 63).

⁴ B. Hansen and M. El Tomy, "The Seasonal Employment Profile in Egyptian Agriculture," *Jour. Develop. Stud.*, July 1965, 1 (4), 404.

dustrial labor fell, despite a big increase in industrial investment—that “over-employment” in Government will persist “because the Government has committed itself to employ *all* university graduates.” But according to a theorem of Professor Georgescu-Roegen an oversized bureaucracy is a normal economic phenomenon *only* in overpopulated economies. So we must continue to classify Egypt as an overpopulated underdeveloped country with a severe employment problem, despite government edicts designed to eliminate unemployment and a high growth rate (8 per cent since 1955) in its industrial sector. And maybe the planners were right, since even the authors would agree that Egyptian industry could siphon off large numbers from the pool of surplus government employees without any loss to national output.

The entire complex problem of the interrelationship between the foreign-trade deficit, inflation, the savings-investment process and planning via direct controls or through a heavy reliance on the price mechanism is brilliantly analyzed in the remainder of the book (Chs. 7-11). As long as Egypt continued to be a planned market economy, the authors favored direct controls as against the price mechanism since the conflict between equity and efficiency tended to create “a shortage economy.” But as the extent of government ownership of industry widened, and all foreign-trade activity was placed under strict government control, “this dilemma simply disappeared” when Egypt, after July 1961, became “an Arab Socialist state.” Writing in late 1963 they attributed whatever difficulties Egypt experienced from its program of deliberate industrialization mainly to “inadequate price policies and to an incompetent and bureaucratic regulation of foreign trade.” But by November 1964, in their preface, the authors concluded that the major problem had become a “general domestic excess of purchasing power” owing mainly to a governmental deficit approaching 12 per cent of GNP. Unfortunately, economic analysis is not sufficient to evaluate the consequences of this policy, since the budget deficit is a “politically given factor,” and so the resultant balance of payments deficit and the entire question of an “equilibrium exchange rate” become “essentially political questions.” Notwithstanding this disclaimer these chapters contain some of the finest economic analysis in the entire book and illustrate “ordinary modern economic theory” at its best.

Not too long ago it could rightly be said that Egypt suffered less from a scarcity of information than from a surfeit of bad statistics. Hansen and Marzouk have gone a long way in giving the student of the Egyptian economy the analysis of the data which was lacking in previous works. But at the very outset they state that what still is needed for a deeper understanding of the economic problems of countries like Egypt is “above all detailed, reliable empirical information—statistical data and descriptions of institutions.” Yet repeatedly they note that the data they need—on prices, employment, production, financial reports, government spending, etc.—are not available. They do not comment on why the more recent data are unavailable, leaving the reader to assume that an inevitable publication lag exists.⁵ But writing in 1965, in the article already cited, Hansen has justifiably complained: “the figures from the 1960 agricultural census are actually available in the Ministry of Agriculture,

⁵ See footnote 3 above.

but it has not been possible for us to make the Ministry release these figures (or even to let us have access to them). This lack of cooperation has forced us to work with the old data." Small reward for such noble efforts.

All in all this book gives a highly competent analysis of recent economic development in the Egyptian economy. Yet it certainly does not replace Issawi's *Egypt in Revolution*. Indeed these two books complement each other quite well, Issawi's being strong on historical description, institutional, and organizational detail, but weak and spotty, and generally deficient, in its application of recent analytical advances. Almost the opposite can be said of the book under review. A general economist who wanted to read but one book on present-day Egypt probably would benefit more from Issawi, but the economist seriously interested in Egyptian economic development will just have to read both and to consult them conjunctly.

WILLIAM O. THWEATT

Development Planning: Lessons of Experience. By ALBERT WATERSTON, WITH C. J. MARTIN, A. T. SCHUMACHER, AND F. A. STEUBER. Baltimore: The Johns Hopkins Press, 1965. Pp. xix, 706. \$10.75.

Albert Waterston's book, based on seven years' study at the World Bank of some fifty country experiences, is a major contribution. Every economist concerned with development planning, whether as a teacher in a university or as a practitioner in development activities, should at least plunge into it. It is a voluminous book, as epitomized by a 58-page appendix listing all of the national development plans for all countries of which the author and his assistants were aware. It reaches some significant conclusions, supported by a wealth of examples; the reader may not find them to be uniformly persuasive, but they certainly demand serious consideration. And it is full of distinctions, observations, proposals, cautions, criticisms, and above all descriptions of individual country experiences, which are sure to be thought-provoking.

There are three main themes. The first is that most low-income countries today are not yet ready to carry out effectively comprehensive development planning. Administrative systems cannot handle both rationalized public investment and guidance for private investment, so they do neither well. Relationships in the econometric models used are unreliable, particularly the capital-output ratio and its implication that raising investment is the way to more rapid growth. Emphasis on aggregative analysis distracts planners from preparing projects and fitting them together, so progress is hobbled by a shortage of sound projects. As a consequence, premature comprehensive plans typically fail or become irrelevant.

On the other hand, a project-by-project approach is likely to lead to misallocations because inconsistent criteria for approving projects are used, and to disruptions or inflation because overall resource constraints have not been checked. Waterston's conclusion is that most underdeveloped countries today will accomplish more if they pursue an intermediate approach—integrated public investment planning. The principal sector priorities for public investment are usually apparent, the investment funds available from budgetary

saving and foreign capital inflows can be readily estimated, and an inventory of possible projects can be quickly adjusted to the sector priorities and available funds using simple administrative and economic criteria. Though comprehensive planning is conceptually preferable, a more practical approach today is to get an integrated program of sound public projects moving ahead vigorously.

A corollary is that plan targets should be realistic even if unpalatably modest. They should not be derived from needs, which are limitless, but from realistic estimates of available resources. Indeed, planners should correct investment proposals in the light of past administrative effectiveness of government agencies, and should insist on prior commitments by political leaders on policies and measures which the government is prepared to adopt.

This first theme clearly deserves serious consideration by everyone concerned with how best to accelerate material progress in low-income countries today. I believe that Waterston has persuasively demonstrated that a major reallocation of planners' efforts is often called for. Relatively less staff time should be devoted to plan formulation, particularly aggregative models and broad sector allocations, and relatively more should be devoted to the two most notable weaknesses limiting performance under the plans—project preparation and evaluation, and implementation procedures. On the other hand, Waterston's prescription to defer the attempt to make development planning comprehensive, and to settle for modest targets quickly attainable through improved public investment practices, seems to me quite unsuited to the urgency of the development problem. Governments of most low-income countries today are seeking substantially accelerated growth rates, not just rationalization of the use of available public funds, and the task of planners is to discover patterns of adjustment in all parts of the economic system which will contribute as much as is economically and politically feasible to this overriding goal. From this standpoint, is it so clearly wrong to set targets on the optimistic side as a stimulus for additional effort and mobilization of resources? Can the right sector priorities and project selection criteria really be established simply without thorough aggregative analysis? While the allocation of planners' efforts should in many cases be shifted in the directions Waterston suggests, it seems to me that the present emphasis in most countries upon comprehensive planning, aggregative analysis, and ambitious targets provides the appropriate foundation for such shifts in planners' efforts.

The second recurrent theme is the crucial importance of implementation as an integral part of the planning process. Preparations for implementation should be made in the design stage—undertaking sector, feasibility, and engineering studies on a broad scale to ensure sufficient sound projects; posing sharp policy alternatives to political leaders to elicit clear policy decisions; identifying specific agency responsibilities, performance targets, and associated policies for implementing parts of the plan; defining time schedules and progress measures for approved projects. Implementation during the plan period should then be checked by clearly established follow-up procedures—a reporting system for projects which emphasizes regularity and promptness even at the cost of limiting the information requested; annual progress evaluation.

ations for cabinet-level consideration; annual plans as the operational links between multiyear objectives and current implementation problems.

Again Waterston's conclusions are persuasively argued. Since his survey implies that most countries are lagging in implementation, there are more negative than positive examples of country experiences in support, but his suggestions of lines to follow in improving implementation seem bound to strike responsive chords among operating planners. One notable gap in his treatment of implementation, however, is that there is no explicit detailed examination of use of policy instruments to guide private development activities. This neglect presumably stems from his emphasis on rationalized public investment planning. But for countries with extensive private activities attempting comprehensive development planning, there are many significant issues to be considered—choosing price adjustments or quantitative controls, preferring instruments with broad or with narrow coverage, determining the mix of consultation procedures and inducement or regulation, accommodating short-run fiscal-monetary adjustments and long-run development stimuli. It would be illuminating to have some lessons of experience on these points too.

The third main theme which runs throughout the book is Waterston's conclusion that the principal obstacles to effective development planning in most low-income countries today are administrative and political, not economic. Accordingly, the last eight of the seventeen chapters deal specifically with administrative and organizational topics. Once again there are many persuasive insights—locating the planning agency in the chief executive's office rather than in the finance ministry or a separate planning ministry, establishing a small cabinet committee for making major planning decisions rather than a large commission with outside members, coordinating all arrangements for foreign technical assistance in a single agency, screening projects by a central working group including representatives of operating ministries, avoiding a separate organization to supervise plan implementation, establishing programming units in operating ministries, and numerous others. I would question whether, given the general administrative constraints which he describes, and his stress on prompt improvement of public investment activities, Waterston has not envisioned too limited a role for the central planning agency itself. Thus he suggests that it should not permit itself to be drawn into preparing projects and sector programs because of difficulties in operating ministries, and should be happy to leave coordination of foreign financial assistance to the ministry of finance, as well as preparation of the annual capital budget. This seems to me an unduly self-denying approach for the agency most actively concerned with obtaining prompt achievements under the plan. But as in the rest of the book, his judgments are bolstered by many examples of country experiences, and must be weighed seriously.

In sum, economists who wish to go beyond theoretical analysis of economic development to its application by today's governments in low-income countries will find reading Waterston's book a most stimulating experience.

PAUL G. CLARK

The Development of Social Overhead Capital in India 1950-60. By J. M. HEALEY. Oxford: Basil Blackwell, 1965. Pp. ix, 180. 35s.

The author describes the growth in India of certain important types of social overhead capital—transport, power, and irrigation—and discusses their sources of financing, methods of pricing, choices of technology and other related matters of policy interest. His intention is to explain their role in the Indian development effort and to shed light on some basic economic and political problems which confront most developing economies.

The study describes how public investment expanded from an initially modest rate to about 7 per cent of national income, representing by the end of the period about 40 per cent of the entire national investment. At the same time profits (surpluses) of public overhead enterprises (with the notable exception of forestation) remained stagnant or declined. This contributed to the relative (and even absolute) decline in government savings during the period, which in turn led to an increasing need to rely on borrowing. Prices and rates for services by the railways and irrigation and power authorities were not rationalized during the period to provide surpluses. In addition, in the case of irrigation and power projects, rapidly rising deficits resulted from the steep rise of interest charges due to a sudden expansion of capacity after 1951 and from the increase in real investment costs as the exploitation of resources for such purposes was extended to less endowed areas.

The author provides a description of some of the failures of the Indian pricing policies as well as general recommendations about the introduction of more rational methods of pricing. In these, however, he is not always consistent. For instance, he correctly recommends that the cost of subsidizing certain rail services (including passenger travel) should be financed—if subsidization is desired—from government general revenues and not with a discriminatory rate structure. At the same time he endorses discriminatory pricing of irrigation water according to size of land holding in order to offset the lack of an adequate progression in rural taxation.

Because of its importance to industrialization, transportation policy is given special attention. The Indian railways failed to meet demand in the second half of the decade because of a number of factors identified in the study, such as the underestimation of the increase in the average length of haul, an excessive rate of replacement of wagon capacity, the failure to eliminate bottlenecks on particular routes, etc. The author properly notes that underpricing of railroad services contributed to demand-induced pressures on the already overburdened rail capacity, but does not identify the long run consequences of the discriminatory underpricing of coal transport which exist even in slack periods and which distort the location of industries and the choice of technology. (As a matter of interest, soon after the close of the decade under investigation the pressure on rail capacity vanished because the planned expansion in traffic failed to materialize.) The question of road versus rail remains unresolved and no previously unknown information is presented which could shed light on this rather difficult problem. However, the discussion of the relationship between road improvement and savings in vehicle operation costs should be of interest to planners.

The last part of the study examines employment policies and technology relevant to irrigation, river valley and construction projects. The author claims that there is an "economic case for raising the wage rates of unskilled project workers since this would raise efficiency more than proportionately." Even if one accepted the rather tenuous statistical evidence on the relationship between wages, workers' calorie intake, and capacity to work, one must still question the meaning of the "economic case." An increase in the calorie intake leaves the labor force just as unskilled as it was before; at best it can increase the supply of unskilled labor measured in efficiency units. The result in a labor surplus economy may turn out to be a net reduction in the number of employed. Thus we are confronted with a pure welfare problem unrecognized by the author: the trade-off between the level of consumption of the employed labor and the rate of employment. Furthermore, higher wage rates may motivate substitution of capital for labor, a result the author seems keen to avoid. In fact, he himself is in favor of increasing labor intensity as much as possible and argues that because of low utilization rates for equipment "mechanized methods have only a narrow economic advantage over manual methods." This may or may not be so, but the evidence is inconclusive. Comparisons are given only on the cost side and not on the benefit side. Yet, because the time needed to complete a project with alternative construction methods will vary with the method, the stream of benefits (revenues) will also begin at correspondingly different dates. Hence, the economic advantage of the alternative technologies can be determined only with the help of present value computations. When interest rates are high, relatively short differences in construction time may be decisive.

In summary, the study does contain interesting and worthwhile material about a crucial period of Indian planning. However, it is more successful in its descriptive parts (though the discussion is mostly based on information made available during the period under investigation which in a book published five years after the terminal year of the study period need not be the case) and somewhat less instructive in its analytical efforts. The latter could have been given more cohesion and greater unity if there had been an attempt to provide for the analysis of the price and investment policies a general frame of reference such as a clarification of the relative weights attached to the diverse purposes of the Indian development effort.

Brandeis University

Trade, Finance, and Development in Pakistan. By J. RUSSELL ANDRUS AND AZIZALI F. MOHAMMED. Stanford, Calif.: Stanford University Press, 1966. Pp. xii, 289. \$8.75.

The title describes this book's contents with some accuracy. Three chapters (81 pages) are concerned with foreign trade, including detailed discussions of principal export crops, the changing pattern of Pakistan's foreign trade, and the balance of payments since 1947. The bulk of the text (170 pages) deals with "finance," both public and private, including central and commercial banking, special problems of agricultural credit, the capital market, and cen-

tral and provincial government finances. Changes in price levels are discussed in a separate chapter. "Development" is the concern of the entire book, though there is nothing to tie together the various aspects that the authors choose to discuss. There is no thesis to the book, and the closest it comes to a framework is in the last chapter, on "Development Planning," which reviews briefly the efforts and results to 1965, when the book was completed. This chapter, which is the one of most general interest, is weakened by the fact that the data on the economy for the Second Plan period were out of date before the book was published. That is a characteristic of all studies dealing with Pakistan, however, since the statistical base has been undergoing a continuing improvement process.

The major changes in the level and composition of imports and exports are reviewed in two chapters. The crucial nature of Pakistan's failure to devalue with the United Kingdom and India in 1949, and the subsequent effects of the Korean War boom, which kept the full effects of the failure to devalue from being felt until 1952-53, are described very well, particularly with regard to the financial and institutional arrangements. The principal features of the overall changes in trade since Partition were: (i) the decline in "traditional" exports in relative and in absolute importance in export earnings; (ii) the emergence of new exports, particularly manufactures of cotton and jute; (iii) the rapid shift in the composition of imports, notably the decline in cotton textiles and other consumer goods, and the rise of metals, and machinery and equipment, both in absolute and in relative terms; and (iv) the shift from exports of foodgrains at and shortly after Partition to heavy imports of foodgrains under PL 480 during the late 1950's and the early 1960's. Overall, there was a brief period during the Korean War boom when export earnings exceeded imports because of unusually high export earnings, and a period in the early to mid-1950's when payments were close to receipts due to tight import controls and a devaluation in 1955. Finally, there was a widening gap between imports and exports in the late 1950's and early 1960's due to the rising flow of foreign aid of various sorts, which financed about 45 per cent of imports during the Second Plan period. Unfortunately there is little reference to the activities in the productive sectors of the economy and to the movements in composition of national expenditure that accompanied and caused the movements in foreign trade levels and composition. The extremely rapid rate of growth of manufacturing industry, the stagnation of agricultural output up to 1959, the sharp increase in the rate of investment and the surge in agricultural growth after 1959, are not associated adequately with the changing patterns and levels of trade. The only policy variable that is discussed in detail is the exchange rate, though there is some discussion of the import control system.

The legal and institutional features of the growth of banking and the increase in money supply and credit are dealt with extensively. Bank deposits and credit expanded rapidly relative to the rest of the economy through the entire period. Government deficits were financed through the banking system in the mid- and late 1950's, and to some extent again in the mid-1960's. Private trade in export crops and in imports was heavily financed by commercial bank credit, but its share in total advances fell over time, as commerce was

gradually being replaced by the rapidly growing manufacturing sector as a claimant on commercial bank credit. There is some discussion of the policy of the State Bank and its relation to the government and to the commercial banking system, but one of the strange features of the book is its failure even to refer to Richard Porter's *Liquidity and Lending* [4], which deals with monetary policy extensively, and which is also one of the best pieces of empirical research yet published on any aspect of Pakistan's economy.

Credit to agriculture is generally not forthcoming from the commercial banking system, and the arrangements to meet the needs of agriculture are discussed in a separate chapter. The cooperatives and the special banks providing agricultural credit are discussed in great detail, as are the system of government loans, and the traditional lending practices from landlords or village moneylenders. Agricultural credit is and has been in a state of bad disrepair, but there is not, to my knowledge, the general consensus that Andrus and Mohammed allege, that "the cooperative represents the ideal machinery not only for dispensing credit but for meeting the marketing, supply, and other service needs of the millions of small agriculturalists in the country" (p. 157). This is really an article of faith with the authors. There is no empirical evidence that suggests that credit needs would be met best by a cooperative movement. The authors argue that cooperatives to pool land and other resources are necessary to attract institutional credit, that only institutional credit can meet agricultural credit needs, and that, due to a lack of such credit, "a landless rural proletariat has emerged and its ranks are continually swelled" (p. 162). The authors reject credit administered through private distributors of capital goods and current inputs as a possible remedy for the problem. The enormous boom in private irrigation tubewells in West Pakistan recently has suggested that credit may have been less of a constraint than profitable investment opportunities for private agricultural investment and availability of capital goods and purchased inputs at reasonable prices.

The small but growing capital markets in Pakistan are discussed to the extent that data allow. Gross business of insurance companies expanded at rates of over 20 per cent per year since the early 1950's, in response to the expanding urban-industrial-commercial sector. Postal savings institutions have been devices for financing government deficits, and their share in financing assets held by the private sector has been rising, notably at the expense of currency. There is a stock exchange, on which new issues are perennially oversubscribed, but it is too sensitive to manipulation by professionals for it to be indicative of any basic characteristics of the economy.

One of the more interesting chapters concerns the behavior of price levels over the period since Partition. The authors' detailed knowledge of the economy, particularly the trade and financial sectors, enables them to give a good discussion of the response of the economy to the pressures of Partition, the cessation of trade with India, the Korean boom and bust, introduction of import licensing in 1953, devaluation in 1955, the control (and later decontrol) policy of the Martial Law government, and the massive inflow of foreign aid into the economy that accompanied the rise in public and private investment in the Second Plan period. The description of the effects of various changes in

supply and demand conditions in the aggregate and for particular sectors, along with the important differences between East and West Pakistan, will prove interesting reading to anyone familiar in broad outline with Pakistan's economy.

Institutional arrangements in government finance are covered in detail. The problem of federalism, with provinces responsible for major development activities but the central government in possession of the major revenue-raising tax authority, is well treated from an historical-institutional point of view. The continuing importance of indirect taxes in total tax revenue and the changing composition within indirect taxes are discussed, though there is no rigorous quantitative analysis used in the two chapters, or, indeed, anywhere in the book. Excise and sales tax receipts grew most rapidly, steadily rising in importance as domestic production and import substitution occurred in major consumer goods. The authors note with approval the ability of the government to hold down the growth of current expenditures, particularly civil administration. The failure of direct taxes on agriculture to rise, which is a central feature of the revenue developments since Partition, is discussed in detail.

The closest the book comes to an overall view of the economy is in the last chapter, though even there history and institutions dominate much of the discussion. The "failure" of the First Plan is outlined briefly. The Second Plan is reviewed, but the data were unfortunately not complete when the authors were writing this chapter, since they relied heavily on the March 1965 version of the Third Plan, for statistics. The evaluation by Andrus and Mohammed is unemotional, but suggests that things were going well, as most observers would agree. Their concern for the future, expressed also in the chapters on trade and the balance of payments, is that with its poor resource base (little known reserves of oil, iron ore, or coal) Pakistan will not be able to cope adequately with her balance-of-payments problems. For all their general orthodoxy on exchange rates and monetary and fiscal policy, the authors do not seem to be able to convince themselves that one can trade for those resources one does not have. The example of Japan as a resource-poor country does not appear to have come to mind.

It is on the issue of trade and the exchange rate that I have most difficulty in agreeing with the authors when they make their occasional forays into interpretive analysis or prescription. They do not like the floating multiple exchange rate system that the Export Bonus scheme introduced, and they say so in no uncertain language (pp. 76-82). They recognize at times that the currency has been and still is overvalued by the official exchange rate, but they do not appreciate how greatly overvalued it is. They appear to be saying that so long as one does not try to correct partially for a general overvaluation, no one will notice it ("The multiple rate features of the Scheme inevitably raise questions regarding the viability of the official par value . . ." [p. 81]). Thus, like the government of Pakistan, they appear to feel that the partial devaluation is a temporary thing, and when the exchange rate is once again unified, it will be unified much closer to the current official rate than to the devalued rate for minor exports (pp. 80-81). With domestic prices of imports averaging

about twice their c.i.f. prices at the official rate in 1964-65 [3], such a view seems most unfounded. The apparent success of the Export Bonus Scheme in getting resources reallocated to the exporting sectors is forgotten when the authors deal with questions of the appropriate exchange rate. They do not relate the performance of the economy in substituting domestic production for imports and in expanding exports to pay for imports, (which problems they see as principal obstacles to future growth) to the price of foreign exchange.

The detailed history of the legal and institutional framework in which trade and finance have developed, which absorbs most of the book, adds to its usefulness as a reference work for the specialist on Pakistan. The passion for detail, unfortunately, tends to stamp out a sense of perspective, particularly since the data for virtually all tables (and there are 51 of them) come from official sources. Availability of data collected by some official agency tends to provide the basis for the discussion. The insurance industry is extremely small, but the government publishes an Insurance Yearbook. Thus, insurance receives considerable attention. As a source of information on Pakistan, however, the book will be extremely valuable, since the authors do include data from sources hard to come by outside Pakistan.

The descriptive nature of the book tends to get out of hand, and the authors do not refer often to the growing body of analytical studies on Pakistan. As mentioned, Porter's excellent monograph on the monetary system [4] is not even in the bibliography. The authors ignore other published studies dealing with subjects they covered: the Export Bonus Scheme [2] (though they do refer to an early and shorter version), the effects of Partition and the development of interwing trade [5], and imports of foodgrains under PL 480 [1].

Because the book is divided so neatly by subject matter, the four chapters on monetary, credit, and capital market phenomena are easily accessible to economists interested in monetary and financial matters. The usefulness of the book to other economists is diluted by its failure to deal with interpretation and analysis of the material that the authors chronicle and describe so well. The book's devotion to detailed history and institutions is its principal strength as an essential book in the library of anyone concerned with the economy of Pakistan and is its principal weakness as a book of general interest.

Technical Assistance in Theory and Practice: The Case of Iran. By JAHANGIR AMUZEGAR. New York: Praeger, 1966. Pp. ix, 275. \$15.00.

Mr. Amuzegar states that the purpose of his book is to "explore the possibilities and limitations of foreign technical assistance in promoting the socio-economic aspiration of the emerging nations from the standpoint of *their* interests and *their* needs." The study is concerned with Iran, and with the technical assistance provided by the U.S. Government aid missions. While thus limited the author believes his analysis and results may be of interest in a more general setting. Amuzegar considers three broad issues: (1) Iran's need for technical assistance and her capacity to accept such aid; (2) the supply and quality of technicians from the United States, and (3) the issues involved in a "rational transfer" of U.S. technology to Iran. To examine these issues he establishes ten criteria of *optimum effectiveness* of an aid program. These criteria have to do with clarity and coherence of program objectives, rational selection and coordination of methods, relation of aid program to host country's overall development effort, quality of foreign technical assistants, ability of advanced nation to supply aid, and other commonsensical notions as to what conditions are necessary to make aid effective. He then examines the U.S. aid program's fifteen years experience (1950-65) in Iran in terms of its success in meeting these criteria.

In most instances the aid program fell well short of acceptable performance. The program was widely and thinly spread over all aspects of the Iranian economy, with no central focus or guiding theme to hold it together. Thus it seemed to go in all directions and to lead nowhere. This, in Amuzegar's opinion, was true even after the extraordinary confusion in Iran associated with the oil crisis of the early 1950's was settled. Neither did the aid program fit with the other development programs that were under way. These difficulties were due in part to high turnover of key staff in the aid agency and in the Iranian government and in part to problems of cooperation between the two groups. Chiefly however they are explained by the failure or even the recognition of the necessity in the aid agency to draw up a coherent, consistent aid program. Thus projects foundered, and even when officially marked completed were generally ineffective.

Given the lack of a neatly worked out program with well defined slots to be filled, an extra heavy burden was placed on individual advisors, most of whom were not up to the task. Amuzegar finds U.S. personnel ill suited in many ways. They were equipped to do a reasonably effective job in the U.S. economy, but were often helpless in a different environment. They were not able to design new and ingenious approaches to problems that would fit easily and neatly into the Iranian economy. Emphasis is placed on the great differences

in culture, in work habits, in social organization, etc. between the two countries, and the difficulties created thereby for the direct application of U.S. technical procedures in the Iranian economy.

Also the aid program has been particularly ineffective with respect to fostering institutional and social change in Iran. This failure is explained by a variety of factors: tendency on the part of many U.S. advisors to advocate a naive transplanting of "free enterprise" and "democracy," reluctance of the aid agency officially to support alteration in institutions and organizations affecting the "national ethos" or the national character of Iran, and the belief in the minds of many Iranians that the whole program was politically inspired and existed simply because of Iran's proximity to the U.S.S.R.

There are numerous other arguments as to how and why the program fell short of meeting the criteria of optimality, but the ones noted are the principal and recurring themes. The central chapters of the book consist of citing examples and evidence elaborating and supporting the fact of failure and its reasons.

There is little doubt that virtually all points made by the author are valid and relevant in a study of the aid program in Iran. They are of course not new, and the reader conversant with aid programs in general will not be at all surprised by Amuzegar's report. The author is clearly *not* aiming a broadside attack against the program, and he presents his case with restraint. One might feel that he gives insufficient attention to the difficulties originating within the Iranian establishment. His Chapter 7—"Cooperation by the Recipient"—is concerned largely with why Iranians did not find aid personnel and the aid program effective. No attention is given, for example, to the continuing reduction in the proportion of oil revenues allocated to development projects nor to the reduction in effectiveness of the Plan Organization. These two events were not only disheartening to many, but contributed markedly to the difficulties involved in planning aid or anything else in Iran. A reader might also get the impression that the first two Iranian Seven Year Plans were much more complete, meaningful documents than they in fact were. It would have been helpful as well had the author discussed the frequently heard allegations of corruption among Iranian officials, and the negative effect that these allegations had on certain aspects (e.g., attracting foreign investment) of the aid program. Though there is this one-sidedness, it is understandable and the explicit points are surely valid. Despite this conclusion, however, the book is disappointing not only because it contains little that is new, but because the author missed opportunities to do something much more constructive than he did.

The major sources of information used by Amuzegar are some 450 completion-of-tour reports written by U.S. technicians on their departure from Iran. He tells us that he accepted these largely at face value (p. 9) despite the fact that he says the reports evidenced "conspicuous simplicity in diagnosing the problems involved or deeper understanding of the solutions required" (p. 219). He also did considerable interviewing and consulted other reports prepared by the aid agency as well. His method is essentially to assert something about the program, and then offer numerous quotes as supporting evidence. Quotations

no matter how numerous or how unanimous in point of view do not constitute clinching argument. In several chapters Amuzegar begins with a bit of analysis that indicates some insight and understanding, but rather than using this analysis to examine an aspect of the aid program he invariably lapses into presenting quotations. As a consequence the reader sees the difficulties pointed up, but is never shown exactly *how* and why such difficulties interfere with the aid programs. Such a demonstration can be made only by examining the operation of projects and the results themselves in a more analytical fashion than that permitted by a quotation-dominated approach.

There is considerable repetition in the book; all his points could have been made equally effective in many fewer pages. This is relevant because a more concise presentation would have permitted consideration of other issues pertinent to his subject within the book. We are told in Chapter 1 that a number of projects (research in seed improvement, agriculture training, public health, etc.) were "worth the effort." Of great interest and importance is the question of why these projects seem to work while most others did not. Indeed we would like to know how the author concluded they were "worth the effort." Similarly some technicians were quite effective. Attention devoted to explaining what—if any—common attributes were found among effective technicians would have added greatly to the effectiveness of his own study. Truistic generalizations on these issues are not very helpful.

Finally, and perhaps most importantly, it seems clear that understanding and appraising a specific aid program must be done in the context of a framework of the whole development process in the given country. A short chapter on the general development effort in Iran would have helped. More troublesome is the fact that the scattered remarks on this subject suggest that the author has yet to work out his own ideas. His discussion at the beginning of Chapter 7, for example, indicates a view about development and the role of aid in development that makes them much simpler and much more mechanical than has been shown in most of the development literature. It is important to examine aid projects against demanding standards, but these standards must emerge from a realistic recognition of our current understanding of economic development, and they do not do this in this book. Consequently much of Amuzegar's criticism reflects the state of our understanding about development rather than the peculiar qualities of a particular aid program. Carefully relating the aid programs to a more sophisticated and complete approach to development would thus be more revealing about the contributions that technical aid can and has made than repeating quotations to the effect that the aid program was confused.

So, for the reader unacquainted with problems of technical aid and interested in a readable survey of these problems, the book has merit. In terms of revealing something about the mechanics of effective aid programs, and of seeking an explanation of exactly how and why certain factors affect an aid program, the book is disappointing.

HENRY J. BRUTON

Williams College

Diagnosis of the Brazilian Crisis. By CELSO FURTADO. Translated by Suzette Macedo. Berkeley and Los Angeles: University of California Press, 1965. Pp. xxiv, 168. \$5.00.

When Celso Furtado was executive head of the Agency for the Development of the Brazilian Northeast and Minister of Planning in the Goulart government, a friendly critic referred to him as a "master reform monger." Now that he is in exile, the reforming fervor he displayed as an administrator manifests itself in his writings. The present essays, he indicates, have a twofold purpose: one is to define the essence of the problem of underdevelopment; the other is to identify the causes of the current crisis in Brazil.

In the first part of the essays, Furtado reveals himself to be a disciple of those who find the essence of underdevelopment to be a conflict between the dynamics of technological change and the rigidities of the social order. This is the Marxist contradiction between productive forces and social relations—only for Marx this contradiction did not acquire revolutionary implications until industrial maturity had been achieved. Until then the bourgeoisie was a progressive social element which favored and promoted social and economic change. Furtado, however, sees this contradiction ripening for *dualistic* underdeveloped countries during the phase of early industrialization. He seems to attribute this to the failure of the bourgeoisie to dethrone the feudal elements. Among the reasons why the bourgeoisie has not predominated are: first industrialization has not proceeded too far and is too centralized geographically due to externalities and internalities to give the bourgeoisie sufficient political and economic power; second, the political organization favors the rural-based traditional oligarchy as opposed to the populous urban centers; third, the industrial interests are intermingled with the landed interests; and fourth, the growth of class consciousness in the working masses is a very slow process in these societies. Under these circumstances, the bourgeoisie and the feudal elements cannot resolve their many antagonistic interests. Instead, an uneasy alliance between them prevents any realistic plan for national development. Apparently, the contradiction is that the social and political structure takes on a rigidity which is not able to meet the changing demands of an increasingly industrialized, urbanized society.

In the second part of the essays, Furtado diagnoses the post-1962 Brazilian crisis. In his view, the crisis was not caused by economic factors per se. The resource base—excepting coal—and the industrial park are seen as being ample to support and induce a rapid rate of growth. However, the dynamic impulse from these sources has been stifled by numerous social rigidities. The traditional oligarchy, entrenched in the rural-biased state machine, has been powerful enough to frustrate those reforms contrary to its interest. The bourgeoisie, limited to relatively few geographic areas such as Sao Paulo, has not been able to provide effective leadership, etc. But the traditional institutions are no longer adequate, for new forces and problems have been emerging. The first of these is the rapid urbanization which has resulted from industrialization, an expanding market for services, and rural stagnation. This heterogeneous urban population has become the decisive new factor in Brazilian po-

litical struggles in that it constitutes the basis for the recent Populist movement. The second is that the standard of living for a great part of the rural population has been decreasing, even during the rapid growth of the 1950's, as a result of the natural exhaustion of soils and the moving of farms inland from the principal consumption centers. In contrast, there is extreme underutilization of arable land on the great estates. Furtado predicts that unless basic changes are introduced into the social structure, the principal one of which would be a political reform aimed at incorporating the working masses into full political activity, the tendency for the rate of growth to decline will continue and structural problems will worsen.

In the final essay, Furtado examines the social and economic contradictions that abound in the Northeast of Brazil. Though this region is one of widespread poverty, the peasants have typically lacked any sense of class consciousness. Poverty was attributed to the cyclical droughts—a force of nature—rather than to the exploitative social institutions. Fazenda workers lived in an isolation from one another that prevented any effective organization to combat the local feudal power. One startling contradiction, Furtado indicates, recently developed in the archaic sugar industry. After long losing out in the domestic market to the more efficient production of the south, new export possibilities arose for this main product in the Northeast after the Cuban Revolution. The estate owners expanded production by usurping the isolated plots of infertile land previously allotted to peasant workers for subsistence crops. As a consequence, the unit cost of sugar increased even though the peasant's real wage had fallen. Driving the peasants from their subsistence plots had far reaching consequences. For the first time, the peasants who were pushed together in small settlements solidified into a political force which was later instrumental in extending the national minimum wage to the estates. But a new contradiction was created. The region is even less economically viable than before. And the rigidities of the present social organization are not likely to change, for neither the peasants nor the feudal groups are now in favor of any realistic reforms.

These essays are with minor exceptions provocative and stimulating. Despite these virtues, however, the product is not entirely satisfactory. The general contradiction theme has the virtue of simplicity, and is deceptively attractive to activists and reformers who are always searching for grand one-stroke solutions. Furtado partially avoids this pitfall by admitting the complexity of any historical situation. He sets out what he thinks are some of the necessary conditions for economic and social progress, but he does not predict that policies toward these ends will be sufficient. Still, the general contradiction theme seems to raise more questions than it provides answers, and may not be testable.

In this reviewer's opinion, Furtado's conclusions regarding Brazil's social and economic development for the coming years are at the same time too optimistic and too pessimistic. Economic factors do not, by themselves, lead to expectations of complete optimism. Furtado exaggerates the ease with which arable land can be brought into efficient use by ignoring the large infrastructure investments that would be required. He also neglects to recognize the im-

portance of the bottleneck created by Brazil's weak capacity to import. Political reform will not readily remove such obstacles. On the other hand, social and political conditions are not as unsatisfactory as he paints them. While Castello Branco's military regime has neither extended political power to the masses nor brought about all of the needed reforms, it has taken some positive steps. For example, land reform is slowly under way. In addition, the fact that many demagogues have lost their political rights may reduce the dangers of extreme populism. The present government has also reduced the rate of inflation from runaway proportions, and the rate of growth of real product per capita has been increased from an average $-.8$ per cent in 1962-64 to an estimated $+2$ per cent or more in 1965. Finally, a new comprehensive economic and social plan is in process of completion. Thus, while we can all share Furtado's desire for more rapid progress and reform, his gloomy predictions do not seem justifiable.

Given these reservations and criticisms, these essays are worthy of attention. For those who would use them as an only source, however, Furtado's statement that "... with the intention of promoting an intellectual mobilization of the left, I wrote the present book ..." (p. xiii) should be sufficient warning.

DONALD HUDDLE

Rice University

Obstacles to Change in Latin America. Edited by CLAUDIO VELIZ. New York and London: Oxford University Press, 1965. Pp. viii, 263. \$6.75.

This book is a collection of essays prepared for a 1965 conference by ten Latin American scholars, most of whom have held responsible administrative positions in national or international development agencies. In a brief introduction Claudio Veliz develops admirably the bases of the views expressed in most of the essays that "the changes which preceded and followed the industrial revolution in Europe . . . [will not] automatically accompany the industrialization of Latin America" and that "the 'classical' Marxist or liberal models of development based on the experience of the more advanced countries of Europe are not applicable to Latin American conditions." The essays, and particularly the Introduction, largely support the model, advanced more than a decade ago by Paul Baran, of the new industrial middle classes joining the landowners in a coalition of property owners who resist the institutional changes which are necessary for rapid economic development.

Five of the essays attempt generalizations concerning Latin America as a whole; these are "Political Aspects of Economic Development in Latin America" by Aníbal Pinto, "Populism and Reform in Latin America" by Torcuato di Tella, "Land Tenure and Development in Latin America" by Jacques Chonchol, "Implications of Foreign Investment in Latin America" by Victor Urquidí, and "Disunity as an Obstacle to Change" by Felipe Herrera. The remaining five essays are concerned with specific countries; these are "Change and Frustration in Chile" by Osvald Sunkel, "Political Obstacles to the Economic Development of Brazil" by Celso Furtado, "The Dynamics of Brazilian

Nationalism" by Hélio Jaguaribe, "Violence and the Break-Up of Tradition in Colombia" by Orlando Fals Borda, and "Mexico: The Lop-Sided Revolution" by Moisés Gonzalez Navarro.

As is indicated by the above list of titles and authors, the book deals largely with the institutional framework within which economic development occurs and is written by experts from the related disciplines of economics, sociology, political science, and history. Together the essays present a sufficient amount of historical-descriptive material to provide, for the economist who is unfamiliar with Latin American history, the background necessary for an appreciation of the importance of the various political issues which are discussed. The book introduces only familiar obstacles to economic development, but it will prove particularly valuable for social scientists from the more developed countries who are interested in obtaining a better understanding of the views of their counterparts in Latin America.

ROBERT L. BENNETT

University of Maryland

The Genesis of Modern Management: a Study of the Industrial Revolution in Great Britain. By SIDNEY POLLARD. Cambridge: Harvard University Press, 1965. Pp. 328. \$7.95.

My heart sank when, upon receipt of this volume, I discovered its subtitle. In a single scholarly generation a subject can be ground and sifted enough to cause feelings of panic and dismay when further research comes from the presses. Considering the output of the last decade on the early British industrial revolution, together with the meagre additions made to either hard or speculative knowledge about it, an injunction might reasonably be sought to relieve the sufferings of the innocent victims who must buy and read these tomes in order to maintain their standings as "experts" or "students of the subject."

The news I have for the scholarly community thus might seem a mixed blessing. Pollard's new book is an interesting contribution in general, and sui generis in management studies. Pollard has brought together historical materials on management development which seemed exhaustive enough to me, but which, he says apologetically, were merely the limits of "the powers of a single pair of eyes." However, the book is a short one—as things go in such matters. Of the 328 pages, 53 are devoted to footnotes and 3 are index. The actual minimal burden is therefore only 272 pages.

Pollard opens new territory on a frontier one had thought was getting near its last wispy margins. His focus is upon the way management in business groped its way into existence with the first requirements of the modern commercial and industrial world, a time when the typical manager owned his own establishment. What manner of man was this "hard-bitten owner of dark, satanic mills . . .?" As Pollard describes the "representative" manager (p. 258). And what, precisely, did management contribute to human progress in this early era?

There are several singular aspects in Pollard's answers to these and similar questions. I list three. First, he eschews the subjects usually classified as en-

trepreneurship, concentrating instead upon the men and tactics involved in internal business control. As a result, we have a close study of how men learned to run factories, mines, public utilities, railways, estates, and commercial ventures of all sorts. We find early efforts to adapt known commercial accounting methods to new uses, to set up enterprises physically in ways which were cost reducing, buildings, inventory organization, locations near water, raw materials and so forth. We see early efforts to build "staff" in manufacturing and to set up standards of managerial performance. These he considers as management functions narrowly defined, and these are what he studies. Second, he uses modern management as his exploratory paradigm as he wades through these historical materials, so that there is little blind writing and the reader is spared mental "wipeout" as the pages proceed and the decades, industries, men, and problems slide past. Third, he watches carefully, again on the basis of the modern paradigm, for management activities of the period, which are not such today, which were sloughed off as British society changed, and he shrewdly shows why management no longer faces these problems.

The result is fresh and useful. Pollard's approach to early labor problems which came as industry grew literally on the top of rural England is an interesting mixture of Karl Polanyi and Karl Marx which yields some good dividends. We see the connection between those ancient disputes and problems of developing "disciplined" labor forces in backward lands today—problems to which M.D. Morris pointed a few years ago to the surprise of the partial-equilibrium chaps who took the supply of labor as "given." Pollard's book adds valuable information on the question of whether or not labor was scarce in the new industries. We also see in his book why modern management is made possible by the development of an industrial society, a fabric around the factory which relieves the manager of the need to have a heart of stone or else make like Robert Owen. Schools, hospitals, relief, transport, sanitation and so forth are now problems of society at large. Much of modern managerial practice was discovered long ago, and much had to be rediscovered painfully in modern times. It was not passed on by the pioneers. Pollard tells us why. As I said, the book is a contribution to our knowledge of the Industrial Revolution in Britain in general, and it is a "must" for students of industrial bureaucracy and its development. The footnotes are at the back of the book, but the page numbers are given in the left-hand margins so that the usual deadly struggle to find the coordinates of the scholarly apparatus in such books will not delay the careful reader here. Since "footnotes at the end" are apparently necessitated by printing costs today, one can only hope that the system used in this book will become general practice.

J. R. T. HUGHES

Northwestern University

Growth and Structure in the Economy of Modern Italy. By GEORGE H. HILDEBRAND. Cambridge: Harvard University Press, 1965. Pp. xx, 475. \$11.95.

There is by now a tradition of studies by American economists on Italy. The latest is Professor Hildebrand's work, the title and size of which make it

appear the most ambitious of all. To title and size alone, however, must any ambition be confined, for this book contributes but little to an understanding of the "Italian case" and its many problems. Still, it is on these problems that the book ought to shed some light. Thus, Part I and a section of the concluding chapter are devoted to a description and interpretation of the growth process in general, from monetary stabilization in the late 'forties to the long boom which, at unprecedented pace and under conditions of internal and external stability, went on until 1962. Parts II and III deal with the persistence of a surplus of labor through the 'fifties and with sectoral and regional inequalities: a lengthy and painstaking analysis of population, labor force and unemployment data and of the evolution of the wage system and a rather summary account of the Southern problem are followed by an attempt to find the common causes of both evils. The concluding chapter examines the recent breakdown of the boom, current issues and future prospects.

The author's commendable intention in approaching these problems—to use economic theory "to illuminate portions of [the] obscure terrain" where history, culture, institutions exert their influence (p. viii)—unfortunately remains unfulfilled. The theory appearing in the book is a demand and supply equilibrium model for the labor market by which the one analytically relevant result of the whole enquiry is reached: that full employment and economic unification were delayed by wage rises in the advanced sector *prior to 1961*. Hildebrand does not argue in terms of the frequently used, and misused, relationship between investment and surplus over wages. His version of the story, largely repetitive of an earlier one presented with greater clarity and vigor by Mrs. Vera Lutz, runs more or less as follows (net of some contradictions). The slow rise of employment (little more than 3 per cent per year, less than 4 per cent for industry) and the persistence of surplus labor in the face of average yearly growth rates of 6 per cent for GDP and nearly 9 per cent for industrial production, together with an "elasticity of output with respect to employment" even higher than in West Germany, point to a labor-saving bias of investment. In the author's opinion this is confirmed and explained by the fact that, notwithstanding surplus labor, industrial wages rose (about 5 per cent a year in money terms, about 3 per cent real, for 1951-61). Wage pressure was made possible by imperfections in the labor market: in the author's view statutory restraints to internal migration prevented the flow of Southern unemployed to the North and were of paramount importance in permitting the upward pressure of wages for unionized labor. True, wages rose much less than output per man, especially in the advanced sectors, so that unit labor costs fell considerably. But this was the result of entrepreneurial counterstrategy to wage rises, i.e., labor-saving investment. Noncompetitive conditions in the advanced sector, on the other hand, allowed entrepreneurs not to pass on the savings in costs to lower prices, reinvesting the higher profits with a "socially uneconomic emphasis upon labor-saving" (p. 370). Thus "anticompetitive determination of labor costs" checked the growth of employment in the advanced sector and diverted scarce capital to labor-saving investment (p. 373 and *passim*), preventing the progress of the weaker sectors and regions.

Such attribution of a major independent responsibility of growth disequilibria in Italy to wage behavior, via factor substitution, is unacceptable. Leaving aside obvious theoretical objections, mention of a few factual points will suffice. (1) Legal restraints, though affecting the transparency of the market, never prevented migration whenever job opportunities were available: migration from South to North, 1951-61, was some 1,200,000 units, half of which occurred in 1959-61, when the boom gathered speed and the unemployment rate fell considerably. (2) Evidence points to some fall of capital-output ratios in Italian industry, with certainly no fall in profit rates: how is this to be reconciled with labor-saving movements along, or shifts of, production functions induced by wages? (3) Labor costs per unit of output fell in Italy relative to those of all other Western industrial countries over the period: should one believe that Italian entrepreneurs were so much better than their foreign colleagues in adapting technical progress to wage movements? (4) Hildebrand, finding any evidence of even limited technical rigidity too scanty, argues that entrepreneurs always find ways to bend technology to factor prices and eliminate rigidities and frowns upon the fast rise of productivity in the Italian advanced sectors (chemicals, metal products, etc.): had wages not risen, he implies, more labor-intensive methods would have been devised. But one should like to be provided with some evidence, even scanty, of more or less full flexibility, *for any given size*, in say, oil refining, steel making, or petrochemical production. At any rate, two factors, neglected by Hildebrand, loom large in accounting for the rapid rise of productivity in Italian industry and especially in its advanced sectors. First, Italian industry after the war was in a position of technical inferiority and began to catch up with the technical advance which had occurred in the West: it was not a matter of substituting factors but of introducing *superior* technologies. Second, in the advanced sectors there is a strict relationship between productivity and scale. It is not by accident that such sectors in Italy show the greatest increase in output, the greatest fall in unit labor costs, and the greatest gains from the export boom.

Failure to see these points prevents an understanding of the whole Italian growth process, which was led by foreign trade, permitted by a lesser increase of wages, relative to productivity, than in most other countries, and speeded up by the interplay between rising demand, investment, and productivity. Lacking, with the one exception examined, an effort of economic analysis and interpretation, what remains is a collection of data, facts, and highly personal opinions. The book can serve as a useful and interesting reference on some matters. But as a source it is neither exhaustive (many official sources or documents are neglected, there is no appraisal of the role of State-controlled enterprises or account of the changing trends of State intervention in the South, etc.), nor always reliable, nor up to date (e.g., 1961 census data are not used). Actually, one has the feeling that most of the book was written before 1959, not only because of the outdated information but also because of the general outlook and the failure to understand the remarkable changes that the structure of the Italian economy and the problems to be faced underwent later. It is thus not surprising that no satisfactory analysis is provided of the recent interruption in the growth process. Among other things, Hildebrand is led to be-

lieve that in Italy monetary policy "would encounter great difficulties in coping with inflation" but "has a somewhat easier task in coping with a fall of effective demand" (pp. 102-3), which is exactly the opposite of what has happened since 1963.

LUIGI SPAVENTA

Perugia University

Polish National Income and Product in 1954, 1955, and 1956. By T. P. ALTON AND A. KORBONSKI, B. MIECZKOWSKI, L. SMOLINSKI. New York: Columbia University Press, 1965. Pp. viii, 252. \$6.00.

This book is the third in line from the Research Project on National Income in East Central Europe of the Institute on East Central Europe at Columbia University, and is part of a larger study on the structure, growth, and performance of Soviet-type economies. This is a result of a team effort and the authors are to be commended for undertaking such an important task and providing us with valuable, painstaking, detailed, and especially well documented summary of their research.

The period surveyed is very significant as Poland was emerging from the Six-Year Plan period, characterized by forced and hastened superindustrialization, flagrant disregard of efficiency, and a low consumption level, into a period when the most striking blunders of the Six-Year Plan were being rectified, and the population was being pacified and wooed by increasing the consumption rate and redirecting some investments to agriculture. The study's purpose is to show the relative contribution of various sectors of production to the GNP and to analyze the relative share of output to final uses. The authors "are not concerned with the rate of growth or with the size of Polish economy in comparison with other economies." First, they set their task in Polish current transaction prices (called current market prices) in order to "show the actual articulation of the various sectors," and second, in adjusted factor cost (taking as point of departure the celebrated contribution by Professor Bergson) "to exhibit the allocation of resources in more meaningful terms than market prices alone permit" and to provide "an insight into the dimension of economic activity" in terms of the services of labor and nonlabor productive agents. The factor cost structure is correctly considered as the fundamental aim of the research whereas "market prices" is essentially an intermediate step.

In order to arrive at GNP (including "nonmaterial" production) by sector of production at factor cost, the adjustment consisted in aggregating for each sector of origin the return to labor and nonlabor productive agents. For the former, actual data were virtually accepted and the latter were derived by distributing the aggregate nonlabor returns among the various sectors according to net (depreciated) current replacement costs of fixed and working capital. The result obtained depends on the size and rationality of the numerator, reliability of capital valuation, the rates and reckoning of turnover of capital, correct estimation of depreciation, and the adopted uniform rate of return to capital in all sectors.

As a result of the imperfection of market prices, mainly because of distorted

incidence of turnover tax and, to some degree, the formal character of accounting profits and subsidies, the relative contributions of sectors of production or of final uses are deemed to be seriously misleading as to the relative significance of these sectors in terms of the services of productive agents utilized by the economy. Admittedly the structure of GNP at market prices is a misleading guide for resource allocation but displays the "articulation of economic activities" and those current prices serve for international comparisons of national product and components. Since the sectoral profits do not reflect correctly the share of profit and returns on capital, the authors argue that it is necessary to attribute to the turnover tax the bulk of the returns to nonlabor productive agents. As a result of the deficiency of market prices, generally one zloty worth of consumer goods reflects a smaller resource cost computed at factor cost than does one zloty of investment goods. The results of revaluating GNP at factor cost are far reaching, to wit at Polish market prices the share of industry was about twice as large as that of agriculture, whereas recomputed at factor cost agriculture becomes a slightly larger sector. Also the weight of housing jumped sharply from about 1.5 per cent at market prices to about 11 per cent at factor cost for at market prices the rental rates are nominal and, in adjusting, allowances were made for a rather high rate of depreciation and a uniform return on capital which due to high capitalization in this sector increased the factor cost sharply. Whereas the share of personal consumption in GNP at market prices amounted to about 60 per cent, at factor cost it was about 55 per cent. But by excluding rental, personal consumption indicates a drastic drop to about 44 per cent of GNP.

The fundamental assumption is that the size of GNP expressed in zlotys is identical whether reckoned at market prices or factor costs and within this total the returns for the services of labor roughly correspond to differences in marginal productivity of labor in various occupations as depicted in the recorded market prices, with the residual fully attributed to the nonlabor productive agents. The authors add "whether other assumptions would have greater merit we leave to the reader to consider." For purposes of factor cost adjustment the turnover tax is identified as a return to nonlabor productive agents. Prices of consumer goods include a differentiated rate of turnover tax which is essentially a device for siphoning off purchasing power from the population. Hence the return to nonlabor productive agents is realized through the medium of consumer prices. Consequently there is a divergence between where the tax originates and where it is collected. The profits in various sectors reflect the pricing policy and are dictated by fiscal convenience and, apart from the nature of profit, they cannot be deemed to be directly related to the contribution of nonlabor factors in given sectors. Profits and subsidies are considered to be of a similar nature to turnover tax. They are accounting categories and their source cannot always be equated with the point where they are extracted. In arriving at the GNP at factor cost, profits less subsidies were lumped together with the turnover tax, and the authors consider this as essentially constituting a net return to state ownership and control. The returns to nonlabor factors consist of return to capital, land, and entrepreneurship. Interest was not identified as a distinct return to capital, distin-

guished from profits and returns to entrepreneurship in adjusting the return to capital. It was assumed that the actual return to agriculture at market prices merely consists of return to labor, and no explicit allowance for land as a productive agent was imputed. Hence the returns to nonlabor factors were essentially attributed to capital (adjustments were made to rectify the meager depreciation charges).

The reader should be particularly grateful to the authors for supplying such elaborate appendixes (about 142 out of 242 pages of text), detailed sources, supporting documentation, estimates, and explanations of the methodology of adjustments. Some of the findings and arguments may be controversial. One could question certain assumptions and wish for more elaborate statement and justification of the assumptions' validity and the rationale behind the treatment of turnover tax as a return to nonlabor factors of production. Nevertheless one is impressed with the solid and sober approach to the problem. Undoubtedly this is a useful contribution even if narrow in scope. The reader should find it particularly interesting since the broader economic implications of the authors' findings will be incorporated in a study of Polish economic growth from 1937 to 1962 in preparation under the auspices of the Institute.

GEORGE R. FEIWEL

University of Tennessee

New England: A Study in Industrial Adjustment. By R. C. ESTALL. New York: Frederick A. Praeger, 1966. Pp. xv, 296. \$7.50.

In the economist's (but probably not the public's) rank ordering of real, potential, and imagined economic ills, regional economic problems come somewhere near the bottom. However, this chronicle of New England industrial experience over the past forty or so years brings out the enormity of the pressures which can be exerted on a regional economy and the adjustments which are required in order to maintain something resembling prosperity. The decline of the textile industry is the most dramatic case in point. Employing 420,000 persons or 30 per cent of the labor force in manufacturing in New England in 1919, the industry declined at an average rate of 8,000 jobs per year for the next forty years. From such declines, recovery is neither easy nor automatic.

Estall offers valuable insights into the problems of recovery and adjustment in mature industrial economies. He examines the fortunes and misfortunes of the major New England industries with separate chapters on textiles, electronics, shoe and leather trades, paper, aircraft, and machinery manufacture. Other industries are treated in less detail. His discussion is largely confined to manufacturing (which for New England is justified) and relies on published data. The location and structure of industry are explained on such bases as wage differentials, availability of required labor skills (particularly R & D expertise), and proximity to markets and raw materials. He does not trace the causal chain beyond this. For example, no attempt is made to explain why wage differentials exist or to explore the reverse effects, those of industry location on wages.

Rather than examining New England as an agglomerate whole, considerable

attention is devoted to the dispersal of industry within the region. New England's early basic industries were widely scattered. The new industries which have tended to rejuvenate the New England economy since World War II have been geographically concentrated, generally being confined to the Boston and western and southwestern Connecticut areas. The remaining areas of New England have received few spillover benefits and remain in considerable distress. Constructing a crude but, nevertheless, ingenious "Index of Relative Dispersal" Estall shows that the five most widely dispersed industries in New England (lumber and wood, pulp and paper, textiles, food and kindred products, and leather) have suffered either absolute declines in employment or are growing at rates substantially below the industry national average. Together, these five industry groups suffered a 25 per cent drop in employment between 1939 and 1958. On the other hand, the five industry groups showing the greatest index of geographic concentration (instruments and related products, electrical machinery, primary metals, transport equipment and ordinance, and miscellaneous manufacturing) had a 98 per cent rise in employment over the same period. Recent growth in New England has indeed been uneven and localized.

Estall concludes with a policy chapter in which he examines the steps taken to alleviate the widespread pockets of distress remaining in New England. Generally, his argument is that there has been too much promotion at the expense of planning, and that local and, to a lesser extent, state governments have inappropriate jurisdictional units and often inadequate resources to carry out effective "self-help" programs. He's probably right.

This book is a fairly good case study of a region and one that should be completely understandable to noneconomists. It may and should stimulate case studies of industrial development and decline for other regions in the United States. Such studies would be of value to geographers, regional planners, transportation economists, and others working in regional economic development. Although readers familiar with the New England economy will already be familiar with much of what this book contains, Estall intertwines many threads and presents an integrated, overall view of the economic geography of the region. Surely, a reading of Estall's book is recommended to anyone working on the economic development of New England.

State University of New York at Buffalo

Statistical Methods; Econometrics; Social Accounting

Operations Research and Quantitative Economics: An Elementary Introduction. By HENRI THEIL, JOHN C. G. BOOT, AND TEUN KLOEK. New York: McGraw-Hill Book Co., 1965. Pp. xiv, 258. \$8.95.

This book presents a survey of the methods and accomplishments of economics and operations research at a nontechnical level. It is written primarily for the nonspecialist with only a high school background in algebra. The authors have selected a number of simple and interesting examples to illustrate the

various techniques. In spite of the statement on the flyleaf (presumably not written by the authors) that the book "integrates econometrics and operations research," the book does not attempt any such integration. Rather, it provides for each of these an independent elementary introduction.

The operations research techniques described are linear programming, input-output analysis, critical path scheduling, queuing theory, production and inventory theory simulation, elementary probability theory, and elementary game theory, all illustrated by numerical examples. For the most part, the mathematically illiterate reader will be able to follow the illustrations and acquire a certain amount of intuitive understanding of the techniques. In a few places, however, such is not the case. For example, the queuing theory chapter uses the "rabbit out-of-the hat" technique to arrive at formulas for the length of line and average waiting time. The reader gets no sense at all of the why's or wherefore's of such formulas. The selection of operations research topics is representative, the main serious omission being dynamic programming.

The econometric chapters include a simple multiplier model, Klein's model of the U.S., forecasting based on econometric macromodels and on input-output models, scatter diagrams, the least squares method, a very brief description of some properties of statistical estimates, and a chapter on the empirical side of consumer behavior which includes a discussion of index numbers, price and income elasticities, and budget surveys. The authors have succeeded in packing in a large number of concepts in a simple yet intuitive manner which is well suited to the purpose of the book.

The book will not prepare the reader to set up and solve models himself, either of the operations research or of the econometric variety. However, this would be too much to expect in so short a book. The authors have provided an "understandable survey," as promised, and it is recommended reading for economists who are interested in a nontechnical bird's-eye-view of econometrics or operations research.

T. M. WHITIN

Wesleyan University

Economic Systems; Planning and Reform; Cooperation

Comparative Economic Systems—Competing Ways to Stability and Growth.

By ALLAN G. GRUCHY. Boston: Houghton Mifflin Company, 1966. Pp. x, 908. \$9.95.

Professor Gruchy's volume is in fact composed of three separate books. After a general introductory discussion of the functions and goals of an economic system, Gruchy examines "Capitalism" in Book One. Capitalism is represented by the United States, Great Britain since 1951, the Federal Republic of Germany, and France. Book Two, entitled "Socialism," deals in considerable detail with two Scandinavian countries (Norway and Sweden) and with the British economy during the six immediate postwar years. Book Three, called "Communism," discusses the Soviet Union and touches on Yu-

goslavia and Mainland China. Each book is a self-contained unit complete with an historical introduction and with appraisals of the system's performance and outlook for the future. A short chapter on trends and prospects of the three competing systems concludes the volume.

The interest in the study of comparative economics has increased substantially during the postwar years, and with the interest, our knowledge of how individual systems operate. Gruchy had to make two difficult decisions: first, the choice of countries to consider; and second, the particular approach to take and the topics to consider in his study of various national economies.

The author's emphasis is on the United States and the Western Socialist countries. If the choice of countries is to be determined by their importance at present and in the near future, as the author claims, one may well argue for more extensive treatment of the recent French and Yugoslav experiences, which are at least as important as Scandinavian Socialism. The French indicative planning has generated more than casual interest in other West European countries and in the United States, and the Yugoslav experiments with market Socialism have been followed by several countries of the Soviet bloc and considered by the Soviet Union itself. Yet the treatment of both France and Yugoslavia is relatively brief.

Gruchy attempts to integrate the historical, ideological, and institutional aspects of the individual economies. The amount of information he succeeds in making available about each within one single volume is amazing: it includes economic history and the history of economic thoughts, political structure, the resource base for economic development, data on output growth and budgets, national income accounts, and one input-output table. Yet I suspect that the student will be at a loss when faced with such *embarras de richesse*. A cross-sectional comparison of such topics as actual resource allocation, price formation, investment decisions, or economic incentive in the three systems considered is rather difficult and this is one of the basic aims of comparative study. The author's concluding chapter on trends and prospects for the three competing systems, where integration and analysis could have been attempted, is very brief.

Both the choice of countries and of topic coverage are of course a matter of taste. Although a carefully chosen series of paperback monographs on individual countries written by experts in the respective fields (for example, Campbell, Lutz, Nove, Waterston) does offer an attractive alternative to a standard text such as Gruchy's, his book will be welcomed by those who prefer to have extensive information on various countries under one cover and who stress the Western-type economies in their comparative systems courses.

GEORGE J. STALLER

Cornell University

Political Economy, a Marxist Textbook. By JOHN EATON. Rev. ed. New York: International Publishers, 1966. Pp. 255. \$5.00.

The reviewer's interest in this revision of an obscure British textbook reflects a quest for extensive supplementary reading, suited to English-speaking undergraduates, in a Marxist counterpart of their own "bourgeois" texts

in *Principles*. Such a source should ideally be at or above the intellectual level of the standard Anglo-American courses. It should be shorter and less erudite than Dobb or Sweezy or Meek. It should be less dated than Marx's or Engels' economic pamphlets, or Boudin's digest of *Das Kapital*. It should poison fewer wells, be at once less vitriolic and less preachy, and be rooted closer to the students' own world, than any Iron Curtain text I have yet seen in translation.

Mr. Eaton's book, probably a cooperative venture in fact, is, for the moment, among the "least worst" of a disappointing lot of candidates. Its tone is generally moderate; it blends (conjectural) history and (Marxist) economic analysis attractively; it is short and reads easily; its author(s) is (are) obviously familiar with standard economics, although the theoretical level seems somewhat lower than the remainder. The book, despite its chalky-pedagogical subtitle, is designed primarily for high-school-level study courses in informal circles of "progressive" workers, whose members and leaders have usually had only tangential contacts with any other sort of economics. As a result, it passes our "intellectual-level" test only marginally, with a graduate B-minus. Its treatment of non-Marxian economics serves as an indicator in this respect. Proportionately much longer than the treatment of Marxism in "bourgeois" counterparts, it is on balance no fairer and its level of competence a shade lower. We may be grateful that the "howling hyena—learned lackey of Wall Street—intellectual running-dog of imperialism" type of criticism is absent. Replacing it is the relative mildness of such strictures as the following (p. 27):

[T]he development of the labour theory of value . . . enabled Marx to show the nature of capitalist exploitation and that capitalism itself was doomed. . . . The defence of capitalism called, therefore, for an attack upon the labour theory of value. Bourgeois theory was quick to sense this and from about 1830 has been in quest of an economic theory that rejected the labour theory of value.

An American re-issue of a 1963 English revision, this text reflects the "competitive coexistence" stand of the Khrushchev period. By contrast, the first edition, reviewed by Abram Harris in the June 1951 issue of this *Review* (pp. 457-59), antedates the demise of Stalin. The differences are staggering, and speak well for the intellectual flexibility of Eaton and his colleagues, if any. The features which raised Professor Harris' blood pressure 15 years ago were, for the most part,

... all spirits, and
Have vanished into air, into thin air.

One might, for example, describe this edition too as bound "in a strait-jacket of the traditional Marxian theories," but the jacket is at least padded. Harris' 1951 collection of specific "horrors" are mostly gone, and an original Foreword (by Emile Burns), dedicating Eaton's book to rescuing the British worker from the "'mixed-economy' and 'right-wing' leaders who wish 'to save British capitalism at the expense of the working class and the colonial peo-

ples' " is gone too. "Modern revisionism," in short, has improved substantially upon a Stalinist original. Potential readers would do well not to await a third edition, which may mirror "the thought of Chairman Mao," unmentioned this time!

Business Fluctuations

Cost, Prices, and Profits: Their Cyclical Relations. By THOR HULTGREN with M. R. PECH. National Bureau of Economic Research Studies in Business Cycles No. 14. New York and London: Columbia University Press, distributor, 1965. Pp. xxvi, 229. \$6.00.

Hultgren has written a book in the best tradition of the National Bureau of Economic Research. It shares in both the virtues and deficiencies of that methodology. This book will become a basic reference on the cyclical behavior of unit costs, prices, and their combined effect on profits and profit margins.

The principal results are by now reasonably familiar, but the solidity of the data basis supplied by Hultgren serves to strengthen the empirical foundations based on Hultgren's earlier pioneering work [2], Soligo [4], O. Eckstein and T. Wilson [1], and myself [3] (the latter three containing econometric studies of labor productivity for the U. S. economy) not to mention several closely related studies using British data. Deflated quarterly sales and costs from the SEC/FTC. *Quarterly Financial Reports for Manufacturing Corporations* for the period 1947-61, benchmarked on annual Federal Reserve Board output indexes, and wholesale prices, provide the basic data. Hultgren's findings are:

(1) Prices rise throughout a cyclical expansion, but most rapidly toward its end. After the cyclical peak, prices continue to rise but at a somewhat slower rate, falling very slightly by the very end of the recession.

(2) Unit costs, principally for labor, typically fall during the early stages of a cyclical recovery and rise moderately in late phases of the expansion. The early cyclical downturn in output is accompanied by the most rapid unit cost increase of any cycle period, while the terminal stages of the recession correspond to modest unit cost declines.

(3) The explanation of this cost behavior depends, by definition, upon average hourly earnings and manhours per unit of output. Earnings increase at all times, but most rapidly when output is expanding. The behavior of manhours per unit of output lies at the core of the observed cyclical pattern in unit costs. Manhours per unit of output (the reciprocal of labor productivity) fall through the expansion phase, but most rapidly during the early recovery phase, while manhours per unit of output stabilize or increase during the early months of a contraction. Finally, overtime is positively correlated with output changes, which tends to reinforce the movements in unit labor cost noted above.

(4) Rising profit margins are concentrated in the expansionary phase—mostly because unit costs fall early in the expansionary phase, and price in-

creases occur late in the expansion. Rising costs rather than falling prices explain why declining profit margins are bunched in the cyclical contraction.

Wesley C. Mitchell's original study, *Business Cycles*, in 1913, emphasized cost-price changes as particularly strategic in generating changes in profit prospects that are basic to business cycles. Hultgren, more than fifty years later, has a more modest purpose; he emphasizes the effect of sales and output on margins. The more restricted scope of Hultgren's inquiry was dictated by the realization that the analysis, based on the reference cycle, specific cycle concept, is inadequate for the development of a reasonably complete cycle model. The reference cycle method of data decomposition provides a valid and often valuable preliminary to analytical explanations. Using it, Hultgren has made a genuine contribution, restricted, however, by his rather strict adherence to the reference cycle concept. *Why* do unit labor costs behave as they do? *Why* do manhours per unit of output follow the pattern actually observed? A dozen specific cycles cannot answer those questions; the econometric studies cited above can in principle provide answers, even though open to numerous trenchant criticisms.

Two matters of research procedure raise questions. First, the main approach used is to establish rates of change during each of ten cycle stages of unequal length. Unless one really believes that these intervals have major analytical significance, which often they do not in my opinion, then the failure to present rates of change per uniform time interval detracts from understanding the process. Second, profits and profit margins are considered net of all costs including depreciation. Since the Treasury regulations have a major influence on permissible depreciation, it would have been advisable to treat out-of-pocket costs separately and thus isolate the influence of arbitrary legal changes.

The antithesis which I have drawn between explanation and description is much too sharp. Truth has not yet yielded to a single methodology in economics. Several flowers should grow; not the least among them should be hybrids which cross NBER thoughtful scepticism and thoughtful treatment of the data, and econometric approaches with emphasis on theoretical and empirical explanation.

**Money, Credit and Banking; Monetary Policy;
Consumer Finance; Mortgage Credit**

Introduction to the Analysis and Institutions of Money and Banking. By WILLIAM J. FRAZER, JR. and WILLIAM P. YOHE. Princeton: Van Nostrand, 1966. Pp. xi, 682. \$10.75.

An undergraduate text in money and banking, this book is unusual both in the depth of its coverage and in the sophistication of its approach. The exposition proceeds via a succession of linear algebraic models and well-focused institutional interludes, culminating in lucid analyses of (1) the principles of economic policy (*à la* Tinbergen) and (2) complications raised by the existence of lags in monetary policy.

Structurally, Frazer and Yohe cover much the same topics as Chandler's Fourth Edition and in roughly the same order: money and interest; commercial banking and its history in the United States; central banking; macroeconomic theory; international finance; U.S. monetary policy in recent years. But, though the frame is the same, the authors' preoccupation with algebraic models and quantification produces a rather different sort of book.

The strongest chapters are those on U. S. financial institutions, international finance, and the theory of economic policy. These chapters are both well motivated and well conceived. The chapter on the derivation of the Member-Bank Reserve Equation and consolidated Money-Supply Accounts (Ch. 9) is particularly good and deserves a place on graduate reading lists everywhere.

On the other hand, the chapters on monetary and national-income theory are somewhat less successful. The difficulty is primarily one of vocabulary and focus. For an undergraduate textbook, there is to my mind excessive use of hard-to-explain professional jargon and excessive concern with subsidiary behavioral detail. This latter concern blurs the overall flow of the theory and gives the book an unnecessarily ponderous and unwieldy character. In particular, extensive chapters on investment and consumption theory develop a great many points that are not specifically employed in subsequent chapters, while the LM-IS model (which serves to integrate 150 pages of prior theory) is presented and dismissed in five closely written pages.

Some redress is provided by a series of excellent chapter summaries, but the book is by no means a self-teacher. Still, for those willing to take on the risks and extra work of supplementary assignments and guidance, Frazer and Yohe can promise a livelier and more relevant course.

Boston College

Monetary Policy in a Developing Economy—A Study of the Policies of the Reserve Bank of India and Their Effect on the Operations of the Banking System, 1956-65. By C. K. JOHRI. Calcutta: The World Press Private Ltd., 1965. Pp. 283. Rs 20.

India's First Five Year Plan, which ended in March 1956, was modest in size and imposed little strain on the economy. In fact, price levels actually declined during the period and the nation's foreign exchange position remained

comfortable. The Second Five Year Plan was far more ambitious. Its goal was no less than that of raising real national output by 25 per cent and of creating eight to ten million new jobs. To this end, total planned outlays during the Plan period were to be 72 billion rupees, of which 48 billion were to be spent in the public sector and 24 billion in the private sector. The rate of net investment was to be raised from 7.3 per cent of national income at the beginning of the Plan to 10-11 per cent at the end. It was recognized from the beginning that some monetary expansion would be required to reach expenditure targets. Only 24 billion of the public sector outlays were to be met from the government's current revenues and foreign assistance and another 12 billion by borrowing from the public. This left about 12 billion to be covered through expansion by the Reserve Bank and the commercial banks. It also became clear that an expansion of bank credit would be required to meet expenditure targets in the private sectors.

Such was the environment in which the Reserve Bank operated during the five years following March 1956. The Bank was assigned the dual role of assuring that achievement of Plan objectives would not be hampered by a lack of money and of simultaneously preventing an excessive rise of prices. Moreover, it was expected to prevent any decrease of prices or increase of yields on government securities. The policy was called one of "controlled expansion" but "largely passive expansion" would be more apt. The outcome should surprise no one. The money supply rose 22 per cent and price levels about 30 per cent.

Johri describes in detail the policies followed by the Reserve Bank and traces out their effects on the scheduled banks, which hold about 90 per cent of total deposits in the organized banking sector. He does not attempt to analyze effects on rates of expenditures or on price behavior. Open market policies dominated all other instruments of general monetary management. To prevent their prices from falling, the Reserve Bank purchased passively all the government securities that others were not willing to hold at the selected pattern of prices and yields. Some actions were taken towards the end of the period to raise interest rates on credit to the private sector, but these were probably not very effective in slowing the rate of increase, partly because the actions were not very vigorous and partly because of the dominance of open market policy. Bank rate was raised only from 3 to 4 per cent. The imposition of borrowing quotas on banks and levying of penalty rates on borrowings in excess of quotas were of little effect, largely because banks could replenish their reserves by selling government securities. In March 1960 the Reserve Bank imposed marginal reserve requirements, obligating banks to hold increased reserves equal to 25 per cent of the increase of their liabilities after that date. In May these were raised to 50 per cent. These actions appeared to be slightly restrictive, but they were rescinded ten months later because they were restricting "the availability of credit for the legitimate needs of industry and trade"

Selective controls, embodying margin requirements and quantity limitations, were imposed on loans based on food grains, oil seeds, sugar, shares, and certain textiles and fibers. Their purpose was primarily to curb speculation in

these commodities and to limit increases in their prices. Johri concludes that they probably did influence the distribution of credit but that they did little to limit the total quantity of credit or price increases on the selected commodities.

In Appendix I Johri discusses briefly monetary policies during the first three years of the Third Five Year Plan, 1961-1964. During this period the Reserve Bank did allow some increase in interest rates. In general, however, it continued its policy of passive purchases of government securities. The Treasury bill rate actually declined while yields on consols were allowed to rise by about one-half of 1 per cent. These policies were accompanied by a 31 per cent further increase in the money supply, a percentage increase nearly equal to that during the preceding five years.

Johri's detailed study of Indian monetary policies during the Second Five Year Plan is a useful addition to the literature on the role of monetary policy in economic development. It does not even attempt to make new theoretical contributions, but it is a competent and judicious case study. It would be of wider interest if he had concentrated less on effects on the banking system and had ventured more into an analysis of the effects of these policies on the development program. Unlike some writers, he does not contend that inflation occurred because the central bank was powerless to prevent it. Rather, inflation was the inevitable consequence of the Reserve Bank's policy of providing almost passively the rising quantities of credit demanded by the government and the private sectors. On the effects of the degree of inflation actually experienced on the development effort he offers only tentative conclusions: "While nothing can be said with complete certainty, it is probably a safe conjecture that the disadvantages have outweighed the beneficial effects of inflation" (p. 34). On the positive side, inflation probably benefited farmers and business and thus improved incentives to produce and assume risks, at least in the short run. On the negative side, it may have contributed to the decline of the incremental ratio of saving to national income from 19 per cent in the three years preceding 1955-56 to 14 per cent in the following three years. It weakened India's competitive position in world markets and contributed to the stagnation of her exports. It encouraged gold smuggling and clandestine capital exports. And, by reducing real incomes of fixed income groups, it militated against welfare objectives of the Plan. Johri recognizes that his study does not provide the basis for firm answers to these questions.

LESTER V. CHANDLER

Princeton University

Money, Banking, and Economic Activity. By GEORGE G. SAUSE. Boston: D. C. Heath, 1966. Pp. xiv, 507. \$8.75.

The basic theme of the book is how the use of money affects the economic welfare of human beings. The author develops this idea by examining the factors which determine the quantity and turnover of money and the methods available to the authorities to control these factors. He shows how the money system affects the economic well-being of the nation through its impact on the

level of GNP, degree of unemployment, rate of economic growth, and level of prices. He then explains how the authorities have attempted to influence the monetary system in order to achieve economic objectives. In a final section, he examines the role of money in international economic relations.

The author's discussion of commercial banking covers both the deposit mechanism and bank portfolio policy. The exposition of the deposit mechanism is lucid but marred by the use of standard terminology (external and internal drains) in a nonstandard way. It is confusing to read (pp. 92 and 95) that a cash withdrawal by domestic depositors (which most writers would term an internal drain)¹ is an external drain and that an internal drain is a cash withdrawal by other banks. The discussion of bank portfolio policy and the bank management problem (of reconciling profitability, solvency, and liquidity) is very brief. In keeping with his emphasis on monetary economics, the author is more interested in showing how bank operating policy affects the public welfare, but this part of the discussion is also brief and may leave some students with the impression that the allocation of resources is affected by bank lending but not by bank purchases of securities (cf. pp. 114-16).

The section on central banking covers the usual material on the structure and service functions of the Federal Reserve and on the instruments of monetary policy. There is a reference to the 1965 law that eliminated the gold certificate requirement for deposits in order to increase the supply of free gold. In spite of the change, deposit expansion continues to be indirectly constrained by the gold reserve requirement on notes for, as the author points out, the demand for Federal Reserve notes is related to the volume of demand deposits. It might also be noted that, given the continuing drain on the gold stock, the gold reserve requirements will ultimately have to be modified or dropped (either by Congress or by the Federal Reserve exercising its emergency powers). This is not only because a gold drain could hamper domestic monetary expansion but also because a continuing gold drain (without excess gold reserves) would put the Federal Reserve in the anomalous position of having to contract its Federal Reserve note liabilities without having any direct means for doing so.

In reviewing the principles that govern the United States monetary system, the author correctly stresses that "we rely upon a combination of competition, government regulation, and Federal Reserve influence to direct commercial bank activities in the public interest" (p. 190). He adheres to this view in allotting space for the discussion of the Federal Reserve and (to a lesser extent) of government regulation but not of competition. There is no discussion of the market structure of commercial banking, the nature of market rivalry in banking markets, or the competitive implications of the large number of mergers and entrants in recent years. One of the very few observations about bank competition—and it is incidental to a discussion of deposit mechanics—is that an American bank competes with approximately 13,750 other commercial banks (p. 94). This statement probably does no damage to the discussion

¹ For example, cf. Lester V. Chandler, *The Economics of Money and Banking*, rev. ed., New York 1953, p. 217, or W. H. Steiner, Eli Shapiro, and Ezra Solomon, *Money and Banking*, 4th ed., New York 1958, p. 161.

the deposit mechanism, but it plants in the student's mind a very misleading idea (which the text does not elsewhere correct) about bank competition.

The monetary theory section begins with a clear presentation of the quantity theory in its Fisherian and Cambridge cash balance formulations, and then proceeds to modern income theory, including national income accounting and the determinants of consumption, saving, and investment. Ira Scott's four-part diagram is utilized to assemble the component parts of the Keynesian system and to show the relation between interest rate and income determination. The author considers the similarities and differences in the quantity approach and the income and expenditure approach to monetary theory and finds "the main significance of the two approaches in the different attitudes toward social and political problems exhibited by their respective adherents" (p. 323).

While the author accepts the Gurley-Shaw position that commercial banks are not unique, he would not agree that they are as much like other financial institutions as the critics of the conventional view have suggested. However, he does believe that other financial institutions ought to be considered in a study of monetary economics and he has included a section to discuss their role, types, and relation to monetary theory and policy. He covers various government credit agencies as well as the major private nonbank financial institutions, and (without much elaboration) attributes the government's intervention in the financial market to "a feeling that without some form of government guidance the operation of financial institutions leads to an unsatisfactory allocation of resources" (p. 355). The discussion of the Gurley-Shaw view of financial institutions is useful as far as it goes, but it is brief and perhaps too cryptic on some points. For example, it would have been desirable if the author had elaborated on the statement, not otherwise explained, that open-market operations do affect these [other than commercial bank] institutions" (p. 377).

This is a money and banking text in the traditional mold and, all in all, an acceptable one. Although there are some lapses in the exposition, the author is generally written clearly and with a readable style, and the integration of the material into an organic whole will help the student grasp the big picture as well as the detail. Moreover, in spite of the topics (including some newer developments) that have been omitted or treated too briefly, the coverage is generally adequate, especially for a one-semester course.

DAVID A. ALHADEFF

University of California, Berkeley

Interest Rates and the Cost of Capital in Israel, 1950-1962. By HAIM BEN-SHAHAR. Tubingen: J. C. B. Mohr (Paul Siebeck), 1965. Pp. 136. DM 22.50; paper, DM 18.50.

In its contribution to the stock of a nation's basic economic data, this study published by the List Institute, parallels the achievements of some of the monographs produced in the last generation at the National Bureau of Economic Research. It shows meticulous development of a wealth of commercial bank and government source material which few investigators can achieve. Apart from the information it provides about Israel, the book will be of value

as a guide for those developing series for effective interest rates in other countries where problems of tying of loans to the foreign exchange rate or the cost of living, changes in the terms of loans already outstanding, hidden charges on bank loans, etc., are met.

The author resolves the problem of the significance of interest rate series covering periods of markedly different rates of price increase through (in most cases) the working assumption of perfect foresight; this permits him to deflate each year's effective interest rate by the rise in the price index for investment goods during the year. (The assumption is not so drastic as it may sound, for much of the additional interest burden which raised the effective interest rate above the nominal rate was due to linking the value of the portions of loans still outstanding to the cost-of-living index or the price of the dollar, or both.) The assumption of perfect foresight had to be supplemented by forecasts in estimating the effective interest rates on the portions of loans that were to be still outstanding after the end of the period of observation (1962). While these forecasts (4 per cent annual price increases and a 50 per cent rise in the price of the dollar in 1966) have proved inaccurate, they may have been good estimates of what the parties actually foresaw at the time the loans were contracted; if so, the forecasts led to good estimates of the effective rates—and even better estimates of the real rates—which actually determined the behavior of the market.

In addition to the obvious series, the interest rate series derived include: the cost of the government's borrowing from abroad (the most recent real rate about 12 per cent); the real rates paid by several private sectors for government loans, the chief source of finance for private fixed investment (recently $1\frac{1}{2}$ per cent to $8\frac{1}{2}$ per cent); those for short-term borrowings on the large black (later grey) market for commercial paper (a maximum of 15 per cent but recently 9 per cent). The private sector's required rate of return on capital was found to be best represented by the 17 per cent net-of-tax real annual rate of profit realized on listed stocks held for several years. As in other developing countries, usury laws have kept the real rates charged by banks at extremely low levels—often negative and never over 8 per cent—so that rationing had to be used to equate demand with supply in most years.

While most of the book is devoted to the derivation and description of the various time series, as well as some of the institutional background, the final series of real interest rates are employed to test the Israeli government's policy of subsidizing private investment by re-lending its high-cost foreign borrowings to industry and agriculture at the low interest rates described above. It is argued that the economy should invest enough each year so that the marginal rate of return on investment is no higher than the country's real cost of capital (the 12 per cent on the foreign borrowings described earlier). Offering the government's funds to entrepreneurs at that rate would be unjustified, however, because it would depress the rate of return receivable by private savers—the yield on stocks in particular—and thereby reduce private domestic saving. The alternative of inducing the entrepreneurs to invest in projects that had yields below what the private sector required (through offering them part

of the funds needed for such projects at very low, subsidized interest rates) would avoid this deterrent to domestic savings because it would permit the private investor to continue to earn his customary high yields; in fact, this alternative would increase the rate of private saving, for it implies increased demand for private savings and hence an increasing rate of return on them. While the data were too crude and incomplete to permit a full test of this model, it was found that the low interest rates charged on government loans financing portions of the subsidized investment projects would have permitted the entrepreneur to earn roughly his required 17 per cent rate of return on the *nongovernment* portion of the funds if the project as a whole was yielding the desired minimum rate of 12 per cent. The existence of a rational basis for the Israeli government's investment subsidy program thus tended to be confirmed.

A number of defects justify doubt that this test was usable even in the loose form in which it was applied. The marginal cost of capital to the economy is represented by the 12 per cent average interest cost on the chief foreign loan issues (issues offered continuously to the public in the United States); but these issues' marginal costs seem clearly much above the average cost, since the very high cost of Israel's marketing efforts apparently has added three percentage points to the nominal 5 per cent interest rate paid. This understatement of the cost of capital to the economy may have been compensated, however, by an overstatement of the required rate of return on that capital: the associated additional returns to labor and land (and the tax collector) were, in general, excluded from consideration when the minimum acceptable return on investment (12 per cent) was specified. The admittedly shaky estimate of the required rate of return on private investment (17 per cent) may remain unacceptable despite the device of averaging over several years, for the perverse short-run effects cited—rises in required rate of return (or declining profits) cut stock prices and thereby lead to a *reduced ex post* figure for the required return—can still be present if they appear at the end of the period, and their occurrence gradually over the course of the period in a country undergoing rapid economic and financial development cannot be assumed away. Finally, the real rate of return on the equity funds invested in subsidized projects must have been substantially above the figures estimated because, first (contrary to the author's assumption) the nongovernment funds included some nonequity funds costing much less than the equity portion's required 17 per cent; and, second, many of the subsidized projects must have yielded more than the assumed 12 per cent.

WILLIAM H. WHITE

International Monetary Fund

The Liquidity Structure of Firms and Monetary Economics. By WILLIAM J. FRAZER, JR. Gainesville, Florida: University of Florida Press, 1965. Pp. 91. \$2.00.

Professor Frazer's monograph is another addition to the stock of empirical investigations of the demand for money and near moneys, a stock which of late seems to grow at a much faster rate than the relevant population of mone-

tary economists. The study presents results of a cross-section analysis of firms in the manufacturing sector, with data obtained from the FTC-SEC *Quarterly Financial Report for Manufacturing Corporations*.

His major finding is that cash as a percentage of assets declines as firms increase in size, which he interprets as "empirical support for the proposition that the precautionary demand [for money] rises less than proportionally with wealth (assets)" (p. 86), and, since he finds assets and income (sales) almost perfectly correlated, this further suggests that "ratio of sales to money balances must be rising, at least over some major portion of the domain over which asset sizes actually vary" (p. 86). The decline in the money-sales or money-assets ratio as scale increases coincides with a *rise* in the index of "corporate liquidity" (cash plus near moneys divided by current liabilities) as income or assets increase; as assets (sales) rise, firms do choose greater liquidity, but rely more on "near moneys" (including a reduction of a "negative" near money—bank loans) to meet liquidity needs (at least beyond some minimum size). Frazer's results, then, are generally consistent with the Baumol-Tobin hypothesis of economies of scale in the demand for money, and in general inconsistent with the findings of Meltzer (unit elasticity with respect to income or sales) and Friedman (substantial diseconomies of scale with respect to the demand for money).

Frazer does not explore the basis for these differences between the results of his study and those of Meltzer and Friedman. Indeed, he does not explicitly use the data to test a demand function for money by manufacturing firms but rests content with regressions using the ratio of money to assets as the dependent variable and assets as the independent variable, which yield him negative slope coefficients for quarterly cross-sections covering the period 1958-63, on which he bases the major finding noted.

Several comments about his results may be made. First, Frazer's interpretation of his findings is open to question. He refers throughout to the implications of his results for the "precautionary demand" for money by business firms. However, there is no attempt to separate business holdings of money balances into motivational components, if indeed that would be possible, and we are left to wonder how we can be sure that the economies of scale reflect economies in precautionary balances, rather than in transactions or speculative balances. One could argue, as has been done recently, that in an environment where near moneys dominate money, the only demand for money is for transactions purposes; all precautionary and speculative balances will be held in time deposits, bills, or other near moneys. If this is the case, then Frazer's results are relevant to the transactions demand, not the precautionary demand. Second, too little attention is given to definitional questions. Frazer apparently uses the FTC-SEC definition of "cash" throughout, but nowhere that I could find is the reader told whether this includes or excludes business holdings of bank time deposits or savings shares, a point of some importance in comparing income or wealth elasticities of the demand for money (particularly since his data run through 1963, well into the era of importance of certificates of deposit). Third, there is no analysis of shifts in the estimating parameters of the equations for the cash-assets ratio (or the parameters of the

implicit money demand equation) over time. Intercept values are not given at all, and there is some evidence of changes in the slope parameters from quarter to quarter (p. 21). This might have provided useful information on the significance of interest rates and/or business cycles on the business demand for money. Finally, it is most disappointing to find no attempt by Frazer to explain the difference in his findings from those of Meltzer and Friedman-Schwartz (or their critics). Pay your money and take your choice—economies, diseconomies, or proportionality.

Frazer discusses more than the demand for money in the volume. He relates his findings about the financial structure of firms by asset size to the commercial loan doctrine, the effects of trade credit on monetary policy, bank loans as a source of funds for inventories, and the role of business holdings of governments in tax payments and, as a liquidity source. The discussion of these subjects is informative and interesting.

DAVID J. OTT

Southern Methodist University

Commercial Banking and Regional Development in the United States, 1950-1960. By GEORGE MACESICH. Florida State University Studies, No. 45. Tallahassee: Florida State University, 1965. Pp. xvii, 160. \$5.50.

In this small book, Professor Macesich attempts to tie together some hypotheses regarding Southern economic development and the banking structure of the South. The book is a curious mélange of development theory, assorted thoughts on the competitive structure of banking, and some statistical observations which combined do not substantiate Macesich's conclusions. The book's fatal weakness is that the author's objectives are obscure. The reader's confusion is not abated by a generally pedantic style and some grammatical weaknesses.

The five introductory chapters develop the hypotheses to be tested. It is Macesich's concept that generalized propositions explaining the existence of backward regions (in this case, the South) can be measured through statistical analysis of the performance of the Southern banking system. Chapter 2 is almost in the nature of an aside dealing with the monetary development of the United States; the chapter argues that past errors by various monetary authorities stretching back to before Jackson's war with the Second Bank have taken a peculiar toll of the Southern region. Chapter 3 deals with the background of Federal Reserve regionalism and includes a two-page discussion covering the fact that member banks do not own their District Banks—this insert like many others does not relate to the hypotheses, the statistical observations, nor the conclusions. The author's similar insertions, *a priori* comments, *obiter dicta*, etc., are the basis for the reviewer's comment that the author's purpose is not always clear.

Banking as a business is taken up in Chapter 4. Chapter 5, the best in the book, discusses the legal and structural peculiarities of Southern banking. Macesich deals heavily with the phenomenon of non-par banking and non-membership in the Fed, and correctly demonstrates that both are symptoms of backwardness. But, since over 80 per cent of total deposits in the Sixth

District are in member banks, the total economic impact of these marginal banks is probably not too serious. (In 1966 the Georgia Legislature finally required insurance of the state's fifty, small, nonchartered banks.)

The book's central section deals with various statistical tests to determine whether economic backwardness of an area shows up in banking performance. Chapter 7 demonstrates that member banks located on the periphery of Southern economic centers do not have significantly different earning ratios from those institutions located in metropolitan centers. Chapter 8 demonstrates that Southern banks are neither underloaned, overinvested in government securities, nor nonprogressive in their lending attitudes. Chapter 9, using analysis of variance techniques, demonstrates that Southern member banks as compared to other districts have a higher rate of return on loans, similar return on U.S. securities (why should they be different?), and that there are local differences in loan markets. Using T. W. Schultz's hypothesis that industrial areas have a higher degree of economic efficiency than rural, less-developed economies, Macesich posits that this would be shown if Southern banks had higher returns than banks in other areas. This is demonstrated in Chapter 10, although the various bank correlation statistical tests have mixed significance level results. He finds that Southern member banks hold more cash and more real estate mortgages and less government securities than non-Southern member banks. In addition, banks in less developed areas earn proportionally more from their loans as compared to total income than do other Federal Reserve District member banks.

Chapter 12 contains a lead sentence so typical of Macesich's style that it is worth quoting: "The evidence and analyses summarized in this chapter suggest that the principal source of member bank earnings is derived from loans" (p. 140). Chapter 13, the last analytical one, shows that member banks in the less developed areas tend to have a lower capital coverage of the higher risk loans than those in the more highly developed areas.

The conclusion reached by Macesich is that monetary and banking forces have helped to create a situation "favorable to economic stagnation." Furthermore, the higher proportion of cash and real estate loans "simply immobilizes needed resources for local development" (p. 156). Macesich holds that many of the views advanced by Schultz, E. Dunn, C. Clark, S. L. McDonald, and B. Ratchford are useful in understanding certain Southern financial phenomena, but that W. H. Nicholls' concept of "Southern Tradition" as being the basis of stagnation is not supported by the evidence.

Because Macesich holds that the legal environment of banking in general tends to encourage stagnation, he ends the book with a few comments on Mr. Saxon, Mr. Patman, and the Fed. While Macesich's remarks do not appear to be germane to the issue, he apparently does support Patman's desire to reform the Federal Reserve System.

To argue that an efficient banking system aids economic development and lowers the risk premium in the saving-lending process hardly seems an important contribution to monetary economics. That interest rate differentials and the resulting incomes of lenders are higher in one area than another is as natural as the economic fact that transportation costs cause geographical

differentials in the prices of goods. All in all, Macesich has not added significantly to the total of knowledge concerning the role of financial institutions in economic development.

ROBERT R. DINCE

University of Georgia

Consumer Credit Finance Charges. By WALLACE P. MORS. NBER Studies in Consumer Instalment Finance No. 12. New York: Columbia University Press for the National Bureau of Economic Research, 1965. Pp. xvii, 133. \$5.00.

Consumer Instalment Credit and Public Policy. By PAUL W. McCracken, JAMES C. T. MAO, and CEDRIC V. FRICKE. Michigan Business Studies Vol. XVII, No. 1. Ann Arbor: Bureau of Business Research, University of Michigan, 1965. Pp. x, 250. \$6.00.

Consumer credit continues to be the subject of lively political and economic controversy. Despite some limitations and faults, these two works are useful contributions to the literature on the subject.

Wallace P. Mors' monograph is part of a National Bureau study of consumer credit that has produced several earlier works and promises more. It describes the methods U.S. financing agencies and sellers utilize in computing and quoting charges to consumers, explores the uses of the various types of information available, considers problems encountered in converting finance charge information to any given form, and reviews evidence regarding consumer knowledge of these charges, both as dollar amounts and as effective rates.

The variety of methods used to compute and quote finance charges can be credited to the usury laws that set maximum interest rates; to legislative sanction of specific procedures when legislatures have exempted some activities from such laws (instalment cash lending) and applied them to other activities not originally subject to the laws (retail instalment financing); to man's ingenuity in striving to lower calculation and other costs; and, perhaps, to the desire to sugarcoat the price of this credit. The three general methods of computing charges include the "add-on method" (the amount owed by the borrower is the amount received plus the finance charge), the "discount method" (the amount received by the borrower is the amount owed less the finance charge), and the "per cent per month of the outstanding balance method" (a procedure that is clear from the name). There are many variants in use such as "monthly add-on," "annual add-on," "monthly add-on plus," etc., though annual add-on, discount, discount plus, and per cent per month are dominant.

Almost all states add to the variety of practice and the problem of assessing actual rates by imposing graduated ceilings as part of small loan laws. Massachusetts, for example, imposes graduated ceilings of $2\frac{1}{2}$ per cent, 2 per cent, $1\frac{3}{4}$ per cent, and $\frac{3}{4}$ per cent per month respectively on the parts of the loan under \$200, from \$200 to \$600, from \$600 to \$1000, and from \$1000 to \$3000.

Mors presents this picture plus much related information and considers

problems in effecting a desirable standardization. Appendix B provides a table for converting various add-on and discount rates to alternative types of effective rates. The book contains an almost indispensable glossary and a helpful index.

A few qualifications to a generally favorable recommendation are called for. The organization and exposition require that the reader pay careful attention to terms and cross-check some material discussed partly in one section and partly in another. Some of the analysis and discussion is vaguely disquieting. For example, the consumer cannot and does not borrow, say, the full cost of a durable with repayment over the lifetime of the durable with no effect on the rate. How do changes in the various dimensions of the loans available affect his behavior? Investment theory has been moving away recently from the assumption of a perfect market and identical borrowing and investing rates, and has always contained *ad hoc* treatments of the more various market phenomena. Mors' discussion, which builds on an earlier work by Juster and Shay, is not actually unsatisfactory, but the statement (p. 47) that "the traditional approach" assumes that a change in interest rates influences demand if and only if it affects monthly payments is true only for a limited, highly tentative literature. The author provides no explanation, only references to other sources, of some important concepts—for example, "constant ratio formula," etc. (p. 62)—which will be familiar to those acquainted with the finance rate literature but not to many readers, including some who have given considerable attention to other aspects of consumer credit. And some who turn to the book, with the "Truth-in-Lending" Bill before Congress in mind, will regret the absence of any policy recommendations.

Policy recommendations, though not on the matter of finance charge information, do appear in the work by Paul W. McCracken, James C. T. Mao, and Cedric V. Fricke which provides the authors' answer to the question: "Should there be direct federal control of the terms on which instalment credit is made available to consumers?" An appendix presents a sixty-page case study by Thomas R. Dyckman of the influence instalment credit had on the 1955 automobile sales year in this country.

After a brief introduction and overview of the instalment credit industry, the authors consider in order: "Do movements in consumer instalment borrowing make the economy significantly more unstable?" "Is direct regulation of instalment borrowing essential for the effective operation of general monetary and credit policy?" "Would government regulation of instalment borrowing enhance the welfare of consumers themselves by curbing their propensity to buy on time?" "Do the lessons from our experience of controls suggest a need for their continuation?" "What are the prospects for the further growth of instalment credit?" Their examination of these questions leads them to the conclusion that peacetime regulation is not desirable.

The book presents estimates of instalment debt outstanding in 1970, information on repossession ratios by length of employment, etc., and much else. A large part of the data was gathered from a variety of other publications including, of course, the lengthy Federal Reserve study in the late 1950's,

though additional material required for a systematic survey of the many aspects of the subject was acquired from "a large sales finance company," individual banks, etc.

The writing style is straightforward but not very lively, the index skimpy. One cannot say that the book offers any startlingly new data or analysis, and it is unlikely to change many economists' views on the desirability of consumer credit controls in peacetime, views which tend to reflect differing propensities to interfere with private markets and differing assessments of the problem of enforcing controls. But the work can certainly serve usefully as a systematic account to which one can refer students, public policy study groups, and all others interested in the subject.

Public Finance; Fiscal Policy

Public Economics. By LEIF JOHANSEN. Amsterdam: North-Holland Publishing Co.; Chicago: Rand McNally and Company, 1965. Pp. ix, 367.

Once in a decade one can hope to find a text that is intelligible to the undergraduate and an education to their professors. Johansen's *Public Economics* not only meets that prescription, it also stands as a complement to established classics in the field such as R. A. Musgrave's *The Theory of Public Finance*, H. Theil's *Optimal Decision Rules for Government and Industry*, and Bent Hansen's *The Theory of Fiscal Policy*. *Public Economics* explicates the field of public finance for the serious student at a level that demands a limited knowledge of calculus; unnecessary notation and needless complexity are skillfully avoided. Explanations are concise, appropriately qualified, and illustrated by a limited number of examples, primarily from the experience of Norway and other European countries.

Johansen has collected and simplified the presentation of a number of problems in public finance which previously could only be derived from extremely scattered and advanced argument in the literature. Thus his treatment of demand for public goods and resulting conflicts over the apportionment of costs gives insight into the pioneering studies of Lindahl, Samuelson, and Arrow at a level that is easily mastered by an undergraduate.¹ His careful explication of fiscal policy in an economy with changing prices cuts through the ambiguous controversy over money illusion that represents the last major exchange on this subject in the literature.² His treatment of the computation of incidence is far clearer than its predecessors: he makes clear in a simple presentation that distributional effects of taxation can only be studied within the context of a

general equilibrium model of the economy. Assumptions that are required to provide an approximate incidence computation are carefully discussed and the author indicates a sophisticated awareness of their limitations.

Public Economics represents the first intermediate textbook in public finance that attempts the level of sophistication that characterizes current intermediate price and national income theory texts. Both the material presented and the method of presentation make it a text that outranks its competitors. The book's quality makes it impossible to be genuinely critical. Instead the book invites suggestions for the development of additional pedagogical material in public finance, and the remainder of this review is devoted to such suggestions.

In the first three chapters of *Public Economics* Johansen discusses problems of stabilization policy with a simple and well manipulated national income model. Chapters 4 and 5, which deal with the public debt and the functions of public budgeting, are the weakest section of the book. Neither the monetary implications of debt nor the recent controversy over the Buchanan view of welfare consequences of debt finance are discussed.³ The discussion of public budgeting entirely neglects the use of the budget as a vehicle for allocating resources within the public sector. Program budgeting, cost effectiveness, and cost benefit analysis are not mentioned. Functional areas of public expenditure and the problems associated with expenditure in particular areas—such as defense, education, and welfare—are superficially treated.

Chapter 6 is an excellent presentation of classic welfare arguments for government intervention in the allocation of resources. The only weakness of this discussion lies in its failure to discuss the paradox of government intervention in decreasing-cost industries—that is, subsidies may provide optimal current use of a facility once it has been built, but operation with a subsidy makes it impossible to use the price system to determine whether demand is sufficient to warrant construction of the facility in the first place; and subsidy creates difficult problems in determining distribution of the tax burden when some members of the population are non-users or when benefits of the public enterprise are local in character.⁴

Chapter 7 is a reasonably comprehensive discussion of taxation. It begins with a quick survey of alternative tax bases, and continues with a detailed discussion of income taxation and consumption taxes. The discussion of the problems of income-splitting, exemptions, capital gains, and depreciation is outstanding. The mathematical treatment of consumption taxes makes the price effects of turnover, value-added, and retail sales taxation clear and intelligible to any reader. Two criticisms can be made of Johansen's subsequent treatment of the effects of taxation. First, and most serious, he neglects the effects of changes in the allocation of effort between work and leisure in his discussion

³ See J. M. Buchanan, *Public Principles of the Public Debt*, Homewood, 1958; W. G. Bowen, R. G. Davis and D. H. Kopf, "The Public Debt: A Burden on Future Generations?" *Am. Econ. Rev.*, Sept. 1960, 50, 701-6; and P. A. Diamond, "National Debt in a Neoclassical Growth Model," *Am. Econ. Rev.*, Dec. 1965, 55, 1126-50.

⁴ See A. M. Henderson, "The Pricing of Public Utility Undertakings," *Manchester School*, Sept. 1947, 15, 223-50.

of incidence.⁵ Second, Johansen tends to adopt the misleading partial equilibrium usage of the term tax-shifting rather than the more appropriate shifting concept that is tied to a general equilibrium analysis of tax burden.⁶

Chapter 8 is an interesting discussion of the problems of federal finance, based largely on Norwegian experience. Unfortunately, models of the choice of optimum scale for government functions are not developed.⁷ Nor are grants-in-aid given the treatment they deserve in a book of this level of sophistication.⁸

Largely because the book is so well organized and clearly written, one wishes that Johansen had set his hand to the discussion of several additional topics. A natural subject that would fit within his general framework is the effect of government fiscal and debt policy on investment and economic growth. Additional material related to current questions of tax harmonization would also fit neatly into Johansen's treatment both at the macro level, where a good discussion of foreign trade and stabilization is already developed, and at the micro level, where Johansen aptly develops a partial equilibrium analysis of customs duties. Additional material contrasting price regulation through tax-subsidy arrangements and direct controls would be a useful adjunct to Chapter 6. One would like to see some mention of the psychological impact of taxation in addition to the more traditional models of the incentive impact of taxation.⁹

One cannot forgive the omission of a bibliography from a book of this caliber. American users of the text will find it necessary to supplement the text with a volume of illustrative material concerning the public sector in the United States, such as is now available in several easily accessible sources.¹⁰

Economics of the Property Tax. By DICK NETZER. Washington: Brookings Institution, 1966. Pp. xviii, 326. \$6.75.

Professor Netzer attempts in this, the first major book on property taxation in the United States since Jensen's 1931 classic, to use "the vastly enriched supply of economic data available in recent years" to determine the impact and incidence of the property tax in the aggregate, the significance of the benefit components of the tax, and the effects the tax and geographic differentials in taxation have upon investment, output, industrial location, and

urban development (p. 16). Explicitly excluded from analysis are the theory of tax incidence and capitalization and the history and administration of the tax. "This volume," as Netzer notes, "is *not* a latter-day version of Jensen" (p. ix). Only a brief description of the book's contents and its main strengths and weaknesses is given in this review.

Netzer's analysis is perhaps at its best in the discussion of the economic effects of non-neutral property taxation. In Chapter II he uses a special Census Bureau compilation to estimate the initial impact of property taxes. His estimates reveal that in the aggregate these taxes discriminate both between sectors of the economy and within any given sector. Moreover, there are substantial geographic differentials in property taxes.

In a provocative theoretical discussion of conditions in various industries, Netzer concludes that inter-regional differences in property taxes probably have little effect on industrial location, but that intraregional differences, especially within large metropolitan areas, may seriously distort patterns of economic activity. Similarly, in Chapter IV he argues that differential taxation of different types of property within cities may affect future urban development, particularly urban renewal.

In Chapter III the incidence of the property tax by income groups is estimated using assumptions about each of its component's incidence among producer and consumer groups. The tax is found to be "markedly regressive" in the lowest income levels, but only mildly regressive or proportional above that. However, the benefits financed by the tax are estimated to be "distinctively regressive" throughout. Thus Netzer concludes that on balance the property tax in the aggregate contributes significantly to income equalization, although substantial horizontal inequities exist.

In his general appraisal of property taxation in Chapter VII Netzer argues that "the land component aside, general taxes on consumption or income and a general value added tax seem clearly preferable alternatives on economic grounds to both the housing and business property taxes." He therefore views the relatively high (about unitary) income elasticity of the economic base of the property tax as somewhat of a mixed blessing, since it portends continued heavy reliance on the tax by local governments.

In the eighth and final chapter Netzer discusses four alternative forms of property taxation, but finds none entirely satisfactory. He rejects a tax on annual rather than capital values as distorting resource allocation and being administratively impractical for the United States. Relatively heavier reliance on taxation of site values would lessen misallocation of resources, but would create serious inequities. Finally, both the taxation of incremental land values and "a family of user charges," while attractive on efficiency grounds, would allow only slightly reduced use of the presently defective property tax.

One of this reviewer's chief complaints about this book is that, although the impact and incidence of property taxes in the nation as a whole is largely irrelevant for the evaluation of the property taxes in any one state, geographic differentials in taxation and their economic implications are not discussed until Chapter V. And even in that chapter some of the most important interstate differences in property taxation are left buried in a category which "is a

challenge but very largely consists of non-farm business holdings" (p. 96), though Chapter VI sheds some light on the personality components of this category. Estimating the sectoral impact and the incidence of each state's property taxes is admittedly a Herculean task. Yet this study's aspirations might lead one to expect such estimates.

Further, Netzer has not enjoyed equal success in answering the questions he set for himself. Subject to the above qualifications, his analysis of the impact and incidence of the property tax is informative and his discussion of geographic differentials in taxation and their effects quite provocative. But his evaluations of the benefit components and the investment and output effects of property taxes are less satisfactory.

For example, Netzer states rather categorically that the property tax finances benefits primarily for individuals and that there are no significant benefits associated with most of its business components. He does not consider the benefits a firm receives from expenditures providing services to its employees. This omission reflects the inadequacy of the theoretical literature in this area. Since this conceptual question has never been answered, the assessment of the benefit component of business taxes financing such expenditures is doomed to less than complete success.

In his discussion of the investment and output effects of property taxes, Netzer theorizes about tax-induced substitutions of labor for capital, of human for physical capital, of nondurable for durable consumer goods and housing, and between goods. But these hypotheses are not subjected to significant empirical tests. Thus it can hardly be agreed that Netzer has determined the effects of the tax upon investment and output, though many of the data he has developed would be useful in such a determination.

This book is valuable primarily because Netzer has brought together and synthesized a wealth of material, largely empirical, on property taxation. In so doing he has increased our understanding of property taxes and has facilitated future research on this important tax. One can only regret that Netzer did not direct his efforts more toward theoretical analysis. Quite often one finds hints of novel theoretical insights which unfortunately usually remain implicit.

International Economics

Measuring Transactions Between World Areas. By HERBERT B. WOOLLEY. New York: National Bureau of Economic Research; Columbia Univ. Press, distrib. 1966. Pp. xviii, 157. \$7.50.

Progress in the analysis of world trade and payments is severely hampered by the lack of geographically disaggregated trade and payments data. Our knowledge of trade flows among major world regions was considerably advanced by the publication, in 1942, of Hilgert's pioneering League of Nations study, *The Network of World Trade*. Since about 1950, merchandise trade data by country of origin and destination have been regularly published by the statistical offices of international organizations. However, corresponding

information for service payments and capital flows has not been available. The publication of Herbert B. Woolley's book, the third in the series *Studies in International Economic Relations* issued by the National Bureau of Economic Research, constitutes a further step forward. In addition to refinements in the world merchandise trade matrix, Woolley presents for the first time regional matrices of service transactions, unilateral transfers, and capital movements.

The geographic classification distinguishes eight major world regions: United States, Canada, United Kingdom, Rest of Sterling Area, Continental OEEC countries, Continental Overseas Territories, Latin America, and Other countries; a supplementary category, International Institutions, is added. (From the viewpoint of today's requirements, one would have preferred it if Japan were shown as a separate analytical region.) Transactions matrices are prepared for eleven classes of balance-of-payments items: merchandise valued f.o.b., five types of service payments, private and official unilateral transfers, capital, gold, and the residual (net multilateral settlements and error). Merchandise and service transactions are shown gross and net; the remaining categories are given on a net basis. The data are annual for the period 1950-54. These transactions matrices were distilled from a regional elaboration of balance-of-payments statements for 78 countries, some of which could be taken more or less directly from the *Balance of Payments Yearbook* of the International Monetary Fund, while others had to be modified or newly constructed. Merchandise import data, often available only on a c.i.f. basis, were re-estimated on a f.o.b. basis. Special studies were undertaken of world petroleum trade and transportation payments involving the fleets flying the flags of Panama, Honduras, and Liberia ("flags of convenience").

The goods and services matrices are "two-valued," i.e., two entries are made in each cell, one referring to the transactions as reported by paying countries and the other to the same transactions as reported by receiving countries. This dual approach afforded an essential check in the preparation of the material and suggested a number of problems, which could then be studied more intensively. While the remaining discrepancies are in some instances still large, on the whole the pairs of corresponding records compiled from statements of different reporting countries agree surprisingly well.

Of the three objectives with which Woolley embarked on this project, (1) presentation of the statistical record, (2) description of trade and payments flows in the period covered, and (3) analysis of transactions and testing of hypotheses, the present volume confines itself chiefly to the first, and deals only to a minor extent with the second. The methodological problems encountered in compiling the record and, in particular, the sources of discrepancy between the corresponding entries in the two-valued matrices account for the bulk of the text of this volume. The choice of emphasis was probably wise; the period 1950-54 is now chiefly of historical interest, and a detailed description and analysis of the transactions of that period would not hold the attention of readers chiefly interested in current trade and payments problems. It is to be hoped, however, that this volume will generate sufficient interest in an extension of the record to stimulate Mr. Woolley or other research workers

into continuing this project. It would be particularly valuable for current work on world trade in goods and services to have the respective transactions matrices brought up to date, so as to furnish a sufficient number of observations for statistical time series analysis. Separate records of unilateral transfers, capital movements, gold transactions, and multilateral settlements and error must undoubtedly remain somewhat less reliable than those for goods and services, even with as painstaking an effort as that underlying this volume. Nevertheless, a regional transactions matrix of capital movements, brought up to date, would be a most valuable tool in connection with current discussions of balance-of-payments disequilibria and the adjustment process. All those interested in these questions owe a debt of gratitude to Mr. Woolley and to the National Bureau of Economic Research for having initiated this project.

RUDOLPH R. RHOMBERG

International Monetary Fund

Exchange-Rate Devaluation in a Semi-Industrialized Country: The Experience of Argentina, 1955-61. By CARLOS F. DIAZ ALEJANDRO. Cambridge, Mass.: The M.I.T. Press, 1965. Pp. xiv, 210. \$7.50.

Professor Díaz has tackled a difficult and frustrating task. He has attempted to trace the impact of currency depreciation on a country which, except for brief intervals, has been plagued by acute inflation for a generation or more. While concentrating on the period 1955-61, he has devoted most of his attention to the effects of the unsuccessful stabilization measures announced by President Frondizi in December 1958. These included the complete removal of quantitative restrictions on imports and the introduction of a single exchange rate which was to be permitted to fluctuate without any government commitment to a pegged value.

Under this program, the Argentine peso immediately depreciated sharply, the balance of payments greatly improved, the price level almost flattened out (albeit at a much higher level) and, for a time, all appeared to be going well. But by 1961, the end of the period covered by Díaz, the gains achieved in 1959 and 1960 rapidly began to melt away. The wholesale price level, which had been virtually stationary in 1960, zoomed upward; the balance of payments, which in 1959 and 1960 had achieved a strong surplus position, relapsed into deficit; and the exchange rate, which had been steady since the second quarter of 1959, began a new decline.

Díaz has made a valiant effort to distill what can be learned from this discouraging experience. His first two chapters are a statement, with new ideas of his own, of the theory of devaluation; the next three describe the main characteristics of the Argentine economy that are relevant to his analysis; and the two final chapters review in detail the recent Argentine experience with currency depreciation in an effort to test the theory developed earlier in the volume.

Díaz's exposition of devaluation theory reflects wide acquaintance with the literature and much penetrating thought. His observations about price elastic-

ities, income effects, and the "absorption" approach should impel many a reader to review his own position on these matters. On numerous points, I find myself in hearty agreement. To save space, I shall not dwell on these, but instead shall concentrate on what Díaz clearly regards as his main theoretical contribution—namely, his treatment of the role played in devaluation by changes in the distribution of income.

The author correctly indicates that, for devaluation to improve the balance of payments, it must lead to a reduction in "absorption"—absorption being equivalent to net national product plus the deficit on current international account. The necessary reduction in absorption can be promptly achieved through a cut in domestic expenditure on imports and on "exportables," provided the relevant price elasticities are sufficiently favorable. But here the author encounters a difficulty. He states (p. 10) that "elasticity optimism does not necessarily lead to devaluation optimism," since the initial improvement in the trade balance will lead to an increase in the level of (money) income, thereby leading to increased domestic expenditure on imports and exportables and, consequently, to a new deterioration in the trade balance which may offset much or all of the earlier improvement.

But this, the author assures us, is not the whole story. As a potentially favorable aspect of devaluation, he places great emphasis on what he terms its "redistributive effect." The reasoning, as I understand it, runs as follows: In terms of domestic currency, devaluation raises the cost of living by raising the price level of international goods (imports and exportables). If the pressure to raise money-wage rates can be tightly restrained, there will be shift of real income away from wage earners, whose propensity to save is low, in favor of "capitalists," whose propensity to save is high. By a Keynesian route, this shift in income toward the "saving class" can induce a fall in real output, a consequent fall in absorption, and thus an improvement in the balance of payments. As evidence of such an effect, the author cites a 5 per cent drop in Argentine real output following the sharp depreciation of the peso late in 1958.

While the redistributive effect may in certain cases be a significant (though, in my view, needlessly painful) part of the adjustment process, I am disturbed by the clear implication in Díaz's exposition that a drop in real output is needed, following devaluation, to assure the necessary reduction in absorption. This is surely wrong. What is required is not a drop in real output—this need not and should not occur—but, rather, a drop in real expenditure by the domestic sector. The latter objective will all but certainly be realized, provided the level of money income is prevented from rising by as high a proportion as the devaluation-induced rise in the price level. Subject to this proviso, the real income available to the domestic sector will fall; the domestic demand curves for imports and exportables, however price inelastic, will shift to the left (the degree of shift depending on income elasticity); and a reduction in domestic expenditure on international goods—in other words, a reduction in absorption—will thus be assured. It should be noted that the mechanism here described makes it possible to reverse Díaz's statement about elasticity optimism, and to say instead that "elasticity pessimism does not necessarily lead to devaluation pessimism."

For the mechanism to work, however, devaluation must be accompanied by vigorous anti-inflationary measures to restrain the rise in the level of money income. Díaz's apparent failure to see the need for such measures may account for his decidedly relaxed attitude toward monetary policy. He states (p. 158) that "for the sake of simplicity" he did not deal explicitly with monetary influences in his development of devaluation theory. In view of his puzzling observations about Argentine monetary policy, such an omission would appear to be a serious deficiency. Notwithstanding a 43 per cent increase in the money supply in 1959, the author regards the influence of Argentine monetary policy in that year as "neutral" (p. 159), because the increase was of the same order of magnitude as his estimate of the devaluation-induced rise in the Argentine price level. And despite a 29 per cent increase in the money supply in 1963, he attributes the poor economic performance in that year to what he calls (p. 188) a "most restrictive monetary policy"! With such a philosophy, it is difficult to see how the Argentine inflation could ever come to an end or how currency depreciation could offer more than the most temporary relief.

But I do not wish to end this review on a negative note. On many matters, Díaz's treatment impresses me as eminently competent. I would particularly like to record my emphatic agreement with his subordination of the role played by terms of trade in the post-devaluation adjustment process.

RANDALL HINSHAW

*Johns Hopkins Bologna Center, and
Claremont Graduate School*

The British Balance of Payments. Edited by D. J. ROBERTSON and L. C. HUNTER. Edinburgh and London: Oliver and Boyd, 1966. Pp. vii, 187. 30s; \$4.20.

Seven papers by British academic economists which appeared in 1966 as a symposium in the *Scottish Journal of Political Economy* comprise this volume. These papers are not concerned directly with the recent British balance-of-payments "problem," the resulting pound-sterling crises, or the means available to combat the problem. Rather, these papers may be thought of as providing background information for economists interested in the problems of sterling in the postwar period. For those well versed in the British balance of payments, little new and nothing very exciting will be found here. For those who have only a general notion of the existing U.K. difficulties, this volume will provide an efficient means of deepening and widening their knowledge. Both groups will find a host of previous research conveniently digested in one place.

Individual papers on the broad categories in the balance of payments—exports, imports, invisibles, long-term capital movements, and short-term capital or monetary movements—are included, and two additional papers—one on fiscal policy and the balance of payments, and one on trade with Europe—round out the contents. With one exception (the paper on fiscal policy), the method by which the authors attack their respective topics is essentially the same: a description of the historical movements in the data intertwined with a synthesis of various explanations for those movements. The explanations are

largely those found in existing literature, but sometimes these are buttressed with additional observations and analysis by the authors. While a fairly thorough grounding is thus given in the historical performance of the various components of the balance of payments, the chronic balance of payments disequilibrium which Great Britain has experienced in the past decade is nowhere explicitly attacked *per se*.

Four papers deal essentially with the current account items in the balance of payments. Postwar changes in the amount and composition of exports, imports, and invisible payments and receipts are reviewed in the first three papers. U.K. exports, it is found, have been affected adversely by the geographical pattern of trade, weak sales efforts, and relative price rises in Britain. Imports have risen especially rapidly in periods of full capacity utilization and excess demand, and have failed to fall in the subsequent "stop" period.

Receipts from and payments for services and unilateral transfers are traced from the late 1800's. Adverse factors for the overall balance of payments have been the decline in British shipping receipts and the increase in government transfers; favorable factors have been rising receipts from income on foreign investment and relatively stable balances on travel and "other" accounts. In no case do these three papers attempt to assess the relative contribution of their items to the overall British balance-of-payments problem, nor do they attempt to analyze changes in the structure and relative efficiency of British industry, the impact of economic policy, or other potential causes of the phenomena which they describe.

The fourth paper, on trade with Europe, unexplainably placed at the end, traces postwar developments in the magnitude and composition of exports and imports. Included is an interesting discussion on matters such as the impact of the struggle toward convertibility in Europe and the relaxation of wartime import and payments controls on U.K. trade with European countries in the earlier postwar period. Perhaps most interesting is the treatment of the division of Europe into two trade blocs and the impact of this on British trade. The author concludes that the establishment of a common tariff by the E.E.C. has had relatively little impact, while changes in demand have been much more important in causing changes in the U.K. trade pattern with that group.

A. D. Bain's paper on fiscal policy and the balance of payments deals with a potentially very interesting subject but fails to fulfill completely that potential. The analysis is concerned with the impact of tax structure on export and import competing industries; taxation of income on foreign investments and its effects on capital movements; and the influence of government expenditures on exports and imports. The most intellectually interesting part analyzes domestic taxes as trade distorting devices. The relevant theory is succinctly reviewed, but the evaluation of the U.K. system in light of the theory, is both skimpy and unconvincing, since the international comparisons needed to make the conclusions valid are absent.

The remaining two papers cover developments in the capital accounts. A. G. Kemp's paper on long-term capital movements contains two rewarding discussions, in addition to the summary of historical movements. The first attempts to evaluate the available evidence on the *net* balance-of-payments effect of

U.K. foreign investment. While concluding that foreign investment probably improves the U.K. trade balance, Kemp prudently leaves unanswered the magnitude of this improvement relative to the original capital outflow. The second provides a convenient capsule summary of the recent government actions to suppress capital outflow. With the growing number and complexity of such devices employed by the United Kingdom in recent years, this is a valuable service. Kemp's paper does, however, generate some minor annoyances. For example, he repeatedly writes as if the capital account should be made to adjust to the current-account balance, and ignores the conflict of this view with the traditional transfer theory. He also supposes that one can tell whether foreign investment has been made in lieu of domestic investment or in addition to domestic investment. Unfortunately, his criteria yield question-begging results.

P. M. Oppenheimer's paper on monetary movements and the international status of sterling is the best and the longest. The quality of this paper does not result from a difference in approach from the others, but from a difference of thoroughness. This paper ranges widely over the short-term capital horizon. It touches such topics as the reserve currency status of sterling and how it has changed; the effectiveness of bank-rate and forward-exchange-market policy in altering international short-term money movements; sterling crises and how they occur; and the question of what the impact of the reserve currency status and the sterling area has been on the British balance of payments and British economic policy. Oppenheimer thus comes the closest of any of the writers to treating the "problem" aspect of the British balance of payments. Indeed, he concludes that the international position of sterling has made little difference to the U.K. balance of payments, but has "discouraged policy-makers from going for sensible solutions" presumably implying that a pound devaluation would not cause a world catastrophe.

These essays are prefaced by a brief introduction by D. J. Robertson. Since the various items in the balance of payments are intricately interconnected, the repetition and incomplete integration encountered was scarcely unexpected. The quite unequal length, quality, and sophistication of analysis of the papers, however, may represent a more serious hindrance.

ROBERT G. HAWKINS

New York University

Business Finance; Investment and Security Markets; Insurance

The Stock Market and Economic Efficiency. By WILLIAM J. BAUMOL. The Millar Lectures, Number 6. New York: Fordham University Press, 1965. Pp. xiii, 95. \$3.00.

In these four lectures the author, in his own words, has "tried to explore a wide range of subjects, each of which it was hoped would help us to understand the function of the stock market as an allocator of the economy's capital resources. In the process I have sought to integrate the analysis of the work-

ings of the stock market more closely into the framework of standard economic theory and to incorporate into the discussion a number of segments of the theory of corporation finance."

Specifically, the book consists of stimulating discussions of: (a) the role of the specialist, (b) the determinants of stock prices, and (c) the efficiency of the capital allocation process, prefaced by an introduction, and with a brief appendix discussion of the effect of stock options on the decisions of management and their sense of identification with stockholders. These are all timely and important topics. Moreover, especially as regards (b) and (c) there has been a recent proliferation of both analytical and empirical work, so it is particularly appropriate to assess how far we have come, and what remains to be done. Add to this Professor Baumol's unusual ability to see the broad sweep of economic problems and his expository skill, and it is no surprise that this is a stimulating volume that will have a large audience.

The lectures have an underlying similarity of structure, and a lesson in common. Each starts with an examination of what economic theory has to say about the problem. And in every case it turns out that theory has a great deal to say, but nothing conclusive. In theory, at least, there seem to be countervailing arguments about equally convincing, but leading to very different conclusions for economic behavior and policy. The resolution of this difficulty, therefore, rests with empirical research. This is Baumol's major point which his lectures drive home dramatically and powerfully. He demonstrates convincingly and with wit and wisdom that in fact we know too little about the stock market and associated activities to evaluate the efficiency of the process by which stock prices are determined and capital is allocated among the business enterprises that compete for its use. And thus his call for further research is pointed and meaningful rather than simply the perfunctory amen of the economist's litany. Indeed Baumol goes much further than simple encouragement. He provides a number of interesting specific research suggestions. On this level—an analysis of the issues, a review of what is known, and a statement of what has to be found out—these lectures are eminently successful.

But the author attempts more than this; he feels a responsibility to tell the reader where he stands in the welter of conflicting theory and "fact," and the reasons for his position. Given the state of the field, many such judgments are necessarily matters of taste. To argue about differences in taste is unprofitable. But, in a number of instances, in reaching his judgment, the author relies on a specified set of assumptions, a "model," a view of the world. And these assumptions are not consistent from chapter to chapter. It is in this connection that I find the lectures less satisfactory.

For example, much is made in the lecture on stock price determination of the Miller-Modigliani theorem which proves that "*given the firm's planned investments and future earnings and dividend payments*, it should make no difference to the shareholder whether he receives any dividends or, instead, the company retains these earnings to finance its investments," and a particular elaboration of this proposition—the "true value will out theorem"—which "shows that in the long run, even if a stock offers a relatively low payout rate

and is consistently undervalued by the market, it will yield a full measure of returns to the holder of the security." Indeed these theorems are offered as one of the bases for the "strong reason to suspect that in a rough and ready way, security prices do follow closely the developments in company prospects," despite the fact that because "the long-run competitive mechanism, as ordinarily conceived, functions on the stock exchange only very imperfectly if at all," in this market we cannot expect that the forces summarized under supply and demand would bring about a structure of prices that incorporated this correspondence.

The theorem which proves that dividend policy is irrelevant, is, of course, derived from a set of assumptions and is valid only under these specified conditions. The proof depends essentially on the assumptions associated with perfect markets, including the assumption that there are no taxes.¹

In the next lecture, concerned with the efficiency of the capital allocation process, these assumptions are eschewed, and a more "realistic" set is adopted. Specifically, Baumol notes that the irrelevance of the rate of dividend pay-out "holds only in a perfect world. As imperfections creep in, the scales become unbalanced" and dividend policy is not a matter of indifference. After pointing to a number of these imperfections—major ones being transaction costs and taxes, particularly the differential between the rate on regular income (dividends) and the lower rate on capital gains—he concludes that there are good reasons to hold "that the bulk of business enterprise should finance its investments insofar as possible entirely out of retained earnings *because that is, characteristically, the cheapest way to raise additional funds.*"

What is the reader to make of all this? In one chapter an important reason for the position that the author takes is a theorem based on assumptions of market perfection, among them no taxes. In the next chapter doubt is cast on the realism and relevance of these assumptions and the arguments are based on an imperfect world with taxes. Given their particular assumptions, both the retention argument and the earlier irrelevance theorem are logically correct. But in any particular world they cannot both be valid. This is not primarily a matter of the realism of assumptions, but of consistency in their use. Either the world is perfect or imperfect. Either we have taxes or we don't. Either dividend policy is irrelevant, as in Chapter 3, or consequential as in Chapter 4. To go from one set of assumptions to another at will is to have the ability to prove everything and, hence, nothing.

To end on a critical note would be unfair and misleading. For these lectures accomplish their main purpose in stimulating and instructive fashion. Any one interested in economic theory, financial markets, or business finance should read this book. He will find in it a provocative summary of the state of the

¹ Baumol notes that Miller and Modigliani demonstrate that their theorem can be shown to hold in the face of a number of imperfections if investors behave with "symmetric market rationality," but this does not affect my simple point. Parenthetically, the proof also assumes that the rate at which a dividend stream is discounted is invariant with respect to the time pattern of that stream. Gordon considers that this amounts to "assuming away the fundamental problem." (See Myron J. Gordon, *The Investment, Financing and Valuation of the Corporation*, Homewood 1962, p. 61.)

theory, a useful, albeit necessarily far from complete, account of recent empirical work, and many imaginative suggestions for further research.

Crude Oil Prices in the Middle East: A Study in Oligopolistic Price Behavior. By HELMUT J. FRANK. New York: Frederick A. Praeger, 1966. Pp. xi, 209. \$15.00.

A Financial Analysis of Middle Eastern Oil Concessions: 1901-1965. By ZUHAYR MIKDASHI. New York: Frederick A. Praeger, 1966. Pp. xviii, 340. \$17.50.

Professor Helmut J. Frank's study is divided into two parts. In the first part, he reviews with admirable clarity and detail the evolution of the pricing system. Up to the beginning of World War II, a single basing point system of pricing crude oil prevailed throughout the world. Because of the war conditions, this system gave way to a dual basing point system whereby the supplier of the Middle East oil continued to quote the prevailing prices in the U.S. Gulf of Mexico but charged the actual cost of shipping from the Middle East. The postwar increase in demand for oil and the diminishing importance of the Western Hemisphere as the main supplier of oil provided the impetus for the industry's tremendous expansion in the Middle East. In order to secure new outlets for his oil, the Middle East supplier began in 1950 to post his "own" prices which were lower than those in the U.S. Gulf. This price differential continued to widen during the last decade because of entry, emergence of excess capacity, and the imposition of import restrictions in the United States. Frank concludes that because of these and other developments, the few oligopolists lost control over prices. In the second part, Frank attempts an assessment of the effectiveness of pricing policies with respect to intra-industry and inter-industry allocation of resources.

Although Frank provides us with a good description of the forces which have an impact on pricing policies, the reader is left on his own to judge whether his criteria of effectiveness have been met or not. Moreover, some of his assertions and conclusions cannot be supported either analytically or empirically. Thus we are told that the kink in the oligopolist's demand curve requires the seller to abstain from raising his price. However, since prices were actually raised, we cannot, therefore, say that a kinked demand curve has prevailed (p.141). Frank is also guilty of a major inconsistency in his assessment of the industry's market structure. His conclusion that the oil industry in the Middle East is no longer a tight oligopoly is contradicted by his own assertion that the importance of entry in the Middle East oil industry should not be exaggerated since the newcomers controlled in 1960 only 3.6 per cent of the out-

put (p. 134). Oligopoly is still the best description of a market structure where only eight producers jointly control 96.4 per cent of the output of a standardized commodity.

Professor Zuhayr Mikdashi's volume will impress those who are interested in the economics of Middle East oil as an excellent, straightforward, and comprehensive account of the financial developments which have taken place since the turn of the century. His purpose is to study the determinants of the methods and rates of payment to the host governments of the Middle East and the financial performance of the oil companies. To this end, he painstakingly and diligently plowed through an enormous bibliography of books, official publications, Congressional hearings, company reports, and minutes of negotiations. Also of great interest is the wealth of data which Mikdashi's forty-five tables contain.

The book is divided into three parts to correspond with the three distinct methods of payment. The first part covers the period 1901-32 when payment was based on the integrated profits of the producing company. The second part covers the period 1925-51 when payment was a fixed sum per unit of output. The third and the most important part of the book covers the period 1951-65. During this period the principle of profit sharing was introduced. According to this principle the host governments of Iran, Iraq, Kuwait, and Saudi Arabia receive 50 per cent of the profits realized on the production of crude oil.

A major criticism can be leveled against the importance which Mikdashi attaches to the discounted cash flow method as a measure of the rate of return. Mikdashi apparently fails to distinguish between the use of the DCF method as a tool for capital budgeting and its use as a measure of profitability. Few people will disagree that in its first role the DCF method is superior to the conventional accounting rate of return. Even Mikdashi finds himself forced to abandon his own "scientific" DCF method as a measure of profitability throughout the text except for brief mention on four occasions. Furthermore, his comparison of the DCF rates of return with the accounting rates of return and the conclusions drawn from the comparison are misleading. Thus we are told that the DCF rate of return for Iraq Petroleum Company is only 15 per cent as compared with an accounting rate of return of 56.6 per cent. But Mikdashi is guilty of using two different time periods for his calculations. It is very interesting to note, however, that the two methods produce strikingly similar results when the same time period is used. Thus Mikdashi calculated for the Iranian Consortium for the period 1954-64 the DCF rate of return to be "close to 70 per cent," while the accounting rate of return for the period 1955-64 is calculated to be 69.3 per cent. Had he used, as in this case, the same time period, a meaningful comparison would have been possible.

These criticisms should not, however, detract from the fact that Mikdashi's book is essential reading for any student of the economics of Middle East oil.

ABBAS ALNASRAWI

University of Vermont

Domestic Transportation—Practice, Theory and Policy. By ROY J. SAMPSON and MARTIN T. FARRIS. Boston: Houghton Mifflin Company, 1966. Pp. 464. \$7.95.

In its general plan, organization, and emphasis, this addition to a relatively small but growing list of up-to-date textbooks on transport economics owes an obvious and acknowledged debt to the work of the late Stuart Daggett. Sampson and Farris attempt to treat all modes of inland transport. Their book emphasizes the movement of freight (rather than passengers), and it is written for students of both economics and traffic management.

The book is divided into eight parts. Parts I-III are essentially descriptive. They discuss the importance of transportation, its historical background and evolution in the United States, and the performance characteristics of the different modes viewed primarily from the standpoint of the user. Several chapters provide a detailed description of not only line-haul services but also other-than-line-haul services offered particularly by common carriers.

Parts IV-VI are more largely concerned with analytical problems. They deal with policy questions of current interest and introduce the reader to some important economic issues. Part IV begins with a brief account of the economic and legal basis of rates followed by a simple but useful analysis of the role of demand and costs in the pricing of transport services. This is followed by a concise description of tariffs and freight rate structures. Part IV concludes its discussion of transport rates with two chapters which: (1) emphasize the significance of the relation between transport costs and spatial economic activity, and (2) provide a brief introduction to location theory.

Part V treats the complex history of transport regulation by organizing its discussion around two themes: (1) an initial phase of regulated monopoly which attempted to force the regulated monopolists to compete, and (2) a second phase in which policy was designed to regulate transport competition. A descriptive chapter which summarizes some of the major federal and state regulatory agencies concludes this survey of transport regulation. Part VI considers goals of national transportation policy and emphasizes difficulties created both for definition and realization of these by conflicting interest groups. Part VII, entitled "Transportation Aspects of Physical Distribution Administration," covers topics of particular interest to shippers and traffic managers. A very brief concluding section, Part VIII, looks ahead by emphasizing the significance of further technological change.

The particular mix of analysis, institutional, and descriptive material contained in this text has at least one important drawback. Analysis of transport policy issues is likely to be distorted if passenger transport is neglected since it risks overlooking major determinants of investment in transport facilities. The joint nature of the product of transport facilities, involving both freight and passenger service, should not be ignored in an evaluation of transport policy. Much of the current federal interest in transport policy questions involves problems of investment policy. Pressure for the formation of a Department of Transportation reflects this interest. Also, recent federal government activities involving the planning of integrated passenger transport facilities have been

forced to take the interdependence of freight and passenger services into account, especially in connection with proposed restructuring of railroad networks.

The text is somewhat marred by a tendency of the authors to indulge in obiter dicta that will either antagonize or puzzle sophisticated readers. But, in general, the style of writing is commendable in that the authors' relatively informal exposition and their willingness to make clear and provocative statements should contribute to their goal of stimulating the interest of beginning students in problems of transportation. The plan of the text and its execution suffer to some extent from the attempt to serve sets of readers who have different interests. This leads occasionally to undue brevity in the treatment of details which may be important to the traffic manager, as well as to oversimplification of analysis of broader policy issues. Nevertheless this text has definite areas of strength. It renders its readers a service in stressing the nature of the current regulatory problem which it properly characterizes as one of regulating competition. It also is sound in stressing the significance of the relationship between economic development, transport costs, and freight rates.

In its sometimes overbrief but often judicious discussion of institutional details, the text suggests some of the important and confusing factors affecting the transport industry. This text fails to produce a very clear perspective on the major economic issues of transport economics. But this failure cannot be blamed primarily on the authors. It reflects a general failure to date on the part of economists to produce an analytical framework within which a satisfactory evaluation of modern transport policy issues can be made. Transport economics at best is a very complicated subject. Its complexity is heightened in a pluralistic society, such as in the United States, which gives great scope to the influence of interest groups in the formation of public policies. And rationalization of transport affairs is further complicated by the continuing rapid change in transport technology. This text calls the attention of the reader to many of these problem areas. In this way it is a helpful introduction to a very complex and important area of economics.

Land Economics; Agricultural Economics; Economic Geography; Housing

Water Resource Investment and the Public Interest. By ROBERT H. HAVEMAN. Nashville: Vanderbilt University Press, 1965. Pp. xiii, 199. \$6.00.

Water Resources Development. By E. KUIPER. Washington: Butterworth, 1965. Pp. xi, 483. \$24.50.

These books are concerned with a significant public expenditure category and one which is likely to continue to be of considerable importance in the United States for some years to come. As Haveman notes in his volume, total

federal investment in water resource projects had reached the sum of \$23.5 billion by 1963 with more than half of this amount appropriated since 1950. Furthermore, many more billions of dollars will be sought—and no doubt appropriated—in the near future for water development programs. Hence, any guidelines, criteria, evaluations, etc., that will contribute to a more effective water development program will be most welcomed. Both of these volumes attempt to make such a contribution but in vastly different ways.

Kuiper's book deals with the problem of developing a river system to the greatest benefit of the people who live in the river's drainage system. The emphasis is on the engineering aspects of preliminary project design that will enable sound basin development to proceed from reasonable technical and economic analysis of the alternative project schemes.

In contrast, Haveman's study undertakes to analyze empirically and somewhat theoretically the relationship between the two primary determinants of economic welfare, viz., economic efficiency and income distribution, and incorporates both of them into a multidimensional welfare function as applied to water resource development. "In particular, it attempts to analyze these forces in both their *ex ante* roles as self-contained goals which determine the allocation of water resource appropriations and their *ex post* roles as effecters of changes in social economic welfare" (pp. 9-10).

Kuiper's volume is an excellent treatment of the integrated development of the water resources for an entire basin. The subjects included are water resources planning, hydrology, hydraulics, river morphology, hydraulic structures, flood control, water power, irrigation, navigation, water supply, and economic analysis. Throughout the book the author sets the stage with a broad discussion that puts each subject into proper perspective with respect to the whole work. The treatment of basic principles is necessarily brief but is appropriately well founded on physical reasoning so that it is useful to the engineer who needs a reminder about those principles upon which sound practical analysis rests and it should provide an insight into engineering analysis to the nonengineering reader. The engineering analysis is practical. The limitations and imprecision of all the analytical techniques used for component design and project synthesis are brought to light; however, the author, while not pretending a precision that is not attainable, gives reasonable design criteria and guides so that well-balanced preliminary project designs can be developed.

Kuiper states that it has been his objective to provide sufficient information: (1) to understand the underlying principles and interrelationship of the main elements of river development; (2) to make possible the preliminary design and cost estimates of the required engineering works; (3) to provide guide lines for the selection of the most desirable water plan.

The author has achieved his objective for instructional use with the exception of making possible cost estimates of the required engineering works. There are no adequate data or even guide lines on which to make preliminary cost estimates. This information has to be developed from outside sources. Information is available from which to make cost analyses once project costs have been reliably estimated. The book by itself does not provide adequate

information for preliminary engineering design but it serves as an excellent framework for project planning and preliminary design if it is supplemented with references from its excellent bibliography (35 pages, briefly annotated) and adequate practical engineering background, skill, and resources.

The explanation of engineering analysis and its relationship to economic analysis of water resource development should make this a useful reference to the economist who is interested in understanding the viewpoint and role of the civil engineer in the effective technical and social development of our natural resources.

In his book, Haveman expresses the hope that he is adding to the stream of progress in the area of water resource development begun in the middle 1950's by the studies of Otto Eckstein, John V. Krutilla, and Roland McKean (economists) and Arthur Maass (political scientist). I would also include in this highly selected list of basic studies the three-volume report of the President's Water Resources Policy Commission (1950). The author states that his study is derived from these analyses, and what he has "added is perhaps most simply described as an empirical combination of the two primary determinants of that variable which economists call economic welfare" (p. ix). He then notes that while both the size of the national income and its distribution have been recognized in economic welfare, economists have generally assumed that welfare is a single-valued function of only the size of the national income. He feels that the distinctiveness of his study is the empirical investigation of the relationship between these two welfare determinants and their incorporation into a multidimensional welfare function.

The Haveman study is regional in nature and deals empirically with federal appropriations to the U. S. Army Corps of Engineers for water projects in ten southern states in the years since World War II. In this period, 1951 to 1962, the Corps received some 60 per cent (over \$8 billion) of total federal appropriations for water resource projects.

The rather compact volume consists of six chapters, an epilogue, and three appendixes. In the first section, Chapters 1-3, the nature of the past Corps of Engineers program is described and evaluated. The stated goals of the program are outlined, and an empirical verification of the operation of these motivations is set forth. Chapter 3 considers three key questions pertaining to economic efficiency and income redistribution through water resource projects. (1) Is there evidence that economic efficiency has been an effective Congressional criteria of choice? (2) Can it be inferred that Congress has appropriated a relatively greater share of funds to low income (per capita) states, and does this imply a desire to make use of the water development program as an aid to low income areas? (3) Does the evidence imply that such an attempted redistribution has actually led to less disparity in per capita regional income?

In the second and major section of the study, Chapters 4-6, the two problems of income distribution and economic efficiency (or lack of it) are empirically analyzed in separate chapters and then combined in an attempt to demonstrate the effect of the application of economic efficiency criteria on regional income distribution. The conclusion of this demonstration is that, given the

goal of maximizing the size of the national income, the construction of such projects is an inefficient means of securing a redistribution of income to favored groups.

In the final section, the Epilogue, a rather unorthodox attempt is made to combine both of these primary determinants of changes in economic welfare into a single multidimensional approach. It is concluded that by substituting a multidimensional welfare function for the single-value national income function, it can be demonstrated that the redistribution of income through the construction of some economically inefficient projects may well be a desirable technique.

The three appendixes contain (1) an estimate of the state incidence of federal taxes, (2) a discussion of risk, uncertainty and water resource investment decisions, and (3) data on southern Corps projects.

After careful analysis of the Corps projects in the ten southern states in terms of income redistribution and economic efficiency (Chapters 1-6), he reaches the conclusion that nearly half of the projects, as measured by federal funds committed to the projects, should not have been undertaken as the construction of these projects has led to a misallocation of national resources and economic waste (pp. 117, 123). However, he feels that in terms of economic welfare this conclusion is open to question. "That is to say, conclusions on changes in national or regional welfare have been identified with conclusions on changes in national income only by assuming the existence of a naive welfare function which weights increments of income to each and every recipient equally, i.e., by assuming that the marginal utility of income is equal and constant for every individual" (p. 128). He feels that some new effort must be made to secure a superior technique for evaluating changes in economic welfare.

Haveman tentatively accepts a suggestion made by Eckstein to permit the economist to accept the judgments of policy-makers in assigning unequal weights to the dollar gains and losses to different individuals. "Because such an approach appears to be not only a solution to the economist's ethical problem but also empirically feasible in that it allows real weights to be attached to increments of income to different individuals, it is tentatively accepted as being a superior approach and used in a series of experiments in welfare evaluation" (p. 132). On the basis of different sets of weights he performs two experiments in welfare evaluation and concludes that by substituting a multidimensional welfare function for the single-valued national income function, the construction of some economically inefficient projects may well be desirable.

I certainly agree with Haveman that something more is needed than project evaluation on the basis of economic efficiency and income distribution only. My own view is that financial feasibility is not the same as economic feasibility. While financial costs and returns should be considered most carefully, I believe that they alone should not determine the desirability of a project. A more tenable position, it seems to me, would be for the federal government to seek to conserve and develop the nation's natural resources in such a manner as to provide the broadest and strongest possible foundation for all sorts of

economic activities and to provide the greatest possible scope for all sorts of private investment.

Haveman's study certainly fulfills his expressed hope that it "adds to the stream of progress in this area." Any serious attempt to develop better criteria for the guidance of multibillion dollar public investment in water resources is a most welcome addition to the literature. This is such a study and deserves careful consideration.

JEWELL J. RASMUSSEN*

University of Utah

* Since Kuiper's book deals largely with the engineering aspects of river development, assistance was received from Professor Alan G. Fletcher of the Department of Civil Engineering in reviewing this volume.

The Common Wealth in Ocean Fisheries. By FRANCIS T. CHRISTY, JR., and ANTHONY SCOTT. Baltimore: Johns Hopkins University Press, for Resources for the Future, 1965. Pp. xiii, 281. \$6.00.

Economists who are theorists and/or sport fishermen will find this book a useful introduction to the technology and analysis of commercial ocean fishery exploitation. The essence of a common property resource is the existence of certain social costs of exploitation which are not reflected in the private costs of exploitation. Consequently, a social optimum does not necessarily follow from private maximization. For fisheries, some sort of controls on catch rates and/or entry are required, but such controls are difficult if not impossible to enforce because we are dealing with a resource which is not subject to the complete authority of one national government.

Chapter 3 on the demand for fish shows clearly how the problem of national exploitation of fisheries is complicated by the diverse pattern of demand for fish products. Agreement on mesh size is difficult if in one country the demand is for large members of a species while in another the small members are in demand. Similarly, a control is complicated if in one country the demand is for a predator of a species demanded in another country.

Chapters 4 through 7 provide a competent and thorough discussion of the many aspects of supply—the ecological basis of fish production, the geographical distribution of fish populations, limitations on the potential productivity of the seas (the myth of boundless potential is effectively destroyed), aspects of extinction and depletion of fish populations, the technology of locating, catching, transporting and processing fish, and trends in output of different species by principal countries. Chapter 8 directs the book's treatment of supply and demand to the problem of meeting future demand. The remainder of the book, Chapters 9-13, deals with the problem of control in an international setting.

I find Chapter 2, dealing with the theory of the common-property natural resource as it applies to ocean fishing, the only disappointing part of a good book. It is marred by confusions concerning the relationship between the fish population and the catch under "sustainable yield," i.e., stationary conditions. The graphs reflect this confusion as well as contradictory assumptions which make the graphs inapplicable for comparing the exploitation of a fishery under

sole ownership with that of a fishery under decentralized ownership. Considering the importance of Chapter 2 for economists, it would seem that this review will best serve the authors and readers by devoting the remaining space to a brief restatement of the theory of fishery exploitation.

The technological basis of the theory, in its simplest form (i.e., the analysis of a single fish population without explicit regard for its interaction with other populations), is expressed in the differential equation $\dot{X} = f(X) - P$, where X = fish population in pounds, \dot{X} = time rate of change in population, P = product catch rate, $f(X)$ = "recruitment" rate net of natural mortality. The sustainable yield is defined by the condition that $\dot{X} = 0$, or $P = f(X)$. The ecosystem described by $f(X)$ has the property that when population is low, recruitment net of natural mortality is low; as X increases net recruitment rises to a maximum then declines as natural mortality increases faster than gross recruitment (pp. 7-8). Hence, $f(X)$ has an inverted "U" shape: $f'(X^0) = 0$, $f(0) = f(\bar{X}) = 0$, $f''(X) < 0$, $f(X) > 0$, $0 < X < \bar{X}$, where \bar{X} is the maximum self-sustaining population, and X^0 is the population producing the largest recruitment net of natural mortality (sustainable yield).

Now consider that the fishery is exploited by N homogeneous fishermen with identical operating cost functions, and that the fishery's total output is not large enough to influence price, p . These are the assumptions employed by the authors (p. 10). The most natural hypothesis about operating cost requires it to be an increasing function of the individual fisherman's catch rate x , and a decreasing function of population i.e., $\phi = \phi(x, X)$. Here, we will assume with the authors that the cost function is independent of X , i.e., $\phi = \phi(x)$. We shall also assume explicitly that a minimum profit (or wage) rate, $\hat{\pi}$, is required to hold a fisherman in the industry. Long-run total cost is then $C = \hat{\pi} + \phi(x)$. Also we have $P \equiv Nx$.

In the case of sole ownership, the relevant profit function is $\Pi = pNx - NC(x)$, to be maximized over the decision variables x , N , and X , subject to $f(X) - Nx = \dot{X}$, with $\dot{X} = 0$ if we restrict ourselves to "sustainable yield" analysis. A sole owner has control over X as well as x , and must also decide how many fishermen (boats) will be employed under stationary conditions. The Lagrangian to be maximized is $L = pNx - NC(x) + \lambda [f(X) - Nx]$, giving the conditions: (1) $\lambda = p - C'(x^0)$, (2) $\lambda = p - C(x^0)/x^0$, (3) $\lambda f'(X^0) = 0$. Hence, if $\lambda > 0$, the catch rate of each boat is determined from (1) and (2), i.e., $C'(x^0) = C(x^0)/x^0$, marginal cost = average cost — the usual internal efficiency condition for the multifacility firm with a variable number of facilities. The equilibrium population is determined from (3) giving $f'(X^0) = 0$, i.e., internal efficiency requires the sustainable yield to be maximized. Finally, N is adjusted until Nx , the total catch, is equal to the sustainable yield $f(X^0)$.

The authors attempt to carry through this analysis by postulating aggregate profit, revenue, and cost functions of the form $\Pi(N) = R(N) - C(N)$. We may derive their functions by assuming suboptimization on X^0 , and substituting $x = f(X^0)/N$ into the profit function, i.e., $\Pi(N) = pNx -$

$NC(x) = pf(X^0) - NC[f(X^0)/N]$, which is not consistent with the authors concave revenue and linear cost functions, in the Figures 1, 3, and 4. Also contrary to the above, they conclude that a maximizing sole owner would draw the natural population down to some $X < X^0$.

Applying the same assumptions to the case of decentralized competitive ownership, the profit function for each fisherman is $\pi = px - C(x)$. Profit maximization requires $p = C'(x^*)$. If $p = C'(x^*) > C(x^*)/x^*$, pure profit above $\hat{\pi}$ is enjoyed and additional fishermen enter the fishery. However, under the authors' assumption that price is constant, the increase in N does not lower p , and the situation is represented by the conditions: (4) $p = C'(x^*) > C(x^*)/x^*$, (5) $f(X) - Nx^* = \dot{X}$. But with $\dot{N} > 0$ (firms entering), sooner or later we have $\dot{X} < 0$, until the fishery is exhausted. That is, given the assumption of constant p , there is no escaping the conclusion that the fishery will eventually be exhausted. (There is a trivial exception to this if we have price below average cost. Then $\dot{N} < 0$, and the industry is exhausted as $X \rightarrow \bar{X}$, to the everlasting delight of sport fishermen.)

These criticisms do not, however, alter the validity of the authors' principal conclusion: Under conditions of competitive ownership the exploitation of the fishery is economically inefficient. The reason of course is the externality represented by the population variable, X , which affects the conditions of production for all firms, but does not enter as a decision variable in the individual firm's criterion function. The conclusion holds under the more general cost assumptions mentioned above, where $C = C(x, X)$. In this case long-run firm equilibrium is possible even if p is constant since the entry of firms reduces X and may increase cost until profits fall to $\hat{\pi}$. But a complete analysis of this interesting case, and explicit dynamic treatment of both industry size, N , and the fish population, X , is more appropriate for a research paper than a brief review.

VERNON L. SMITH

Purdue University

Soil Conservation in Perspective. By R. BURNELL HELD AND MARION CLAWSON. Baltimore: The Johns Hopkins Press, for Resources for the Future, Inc., 1965. Pp. xiii, 44. \$7.50.

One aim of the Soil Conservation Service is to help farmers take action to avoid losses in soil productivity that are difficult to reverse after top soil has been eroded away. Though not large in relation to other federal activities, the expenditures are substantial enough (almost \$100 million a year or \$1.5 billion over the past thirty years) that one would have expected a serious evaluation of this effort by now.

In reviewing the history of soil conservation and bringing together the results of numerous previous studies, Held and Clawson give the most complete assessment yet available. The book begins with a rather standard exposition of the economics of soil conservation, followed by a review of the events leading to establishment of the Soil Conservation Service and of changes in the content of the agency program since it was established. Early emphasis was on

soil conservation as usually defined (construction of terraces and contour plowing to control erosion). Before long, the agency added farm planning that substantially changed the enterprise combinations of a farm, as part of the planning assistance offered to farmers. Primarily this type of planning increases present income to farmers. Over the years, still other Department of Agriculture activities were begun that, confusingly, have been labelled soil conservation. These include flood control, payments for using fertilizer, and payments for idling land to control production. The book discusses these activities but appropriately does not give them major attention. Expenditures on them are many times as great as the \$100 million annual expenditures on soil conservation as it is more usually defined. This book is probably the best single source to find out what program content has been, what has been and has not been called soil conservation and why, and what is known about the economic and physical effects of soil conservation activities.

One of the purposes is to juxtapose soil conservation efforts and current agricultural adjustments. The conflicts are emphasized between output-increasing activities and progress to control surplus agricultural production. Yet, the possibility is overlooked that the soil conservation agency may have had a desirable income distributional impact within agriculture. Through farm planning, technical assistance has been carried to farmers who might not have been served by other agencies. The contribution to increasing overall output has been minor compared to other activities including agricultural research and price support programs when prices have been supported without controlling production.

In the middle of the book, on "Performance and Evaluation," the large amount of data available on physical soil conditions is reviewed. The authors stress the still existing lack of useful information, without however offering a serious research agenda for improving the situation. I wish a try had been made to reach more definite conclusions from the summary of studies of returns and costs of soil conservation in various areas. In addition, since the previous studies have lacked a common framework, it would have been useful to spell out the kind of effort that would be required to estimate the returns from soil conservation on a common basis in different areas of the country. The cost of this effort is probably modest. While more research is needed on the effects of erosion on crop yields, it might be concluded that enough is known to obtain fairly reliable results on economic returns without waiting for years of controlled experiments.

The last two chapters concern the future and feature the interplay between the declining political power of agriculture, appeal of the conservation idea relative to other goals, and the need for adaptation by local soil conservation organizations. The tone is that accommodating changes rather than drastic departures will occur, and the recommendations are in this mild vein. The five pages devoted to outlining an ideal program stress the desirability of having more clearly defined soil conservation objectives, better information on the physical effects of conservation, consistency with other programs, more analysis of the economics of conservation and questioning of subsidies. In realistic recognition that the Soil Conservation Service will not limit itself to soil con-

servation as defined narrowly, it is implied that the agency should foster needed agricultural adjustments in addition to promoting soil conservation.

Too frequently throughout the book, the analysis stops at the point where general questions are raised. Instead, in my opinion, definite hypotheses should have been advanced leading to more pointed recommendations. A disappointingly vague conclusion about the condition of the soil is that much has been accomplished but much remains to be done. Would it not be better to recommend a benefit-cost analysis for measures on all farms aided by the Soil Conservation Service, as an operational way of trying to undertake only worthwhile conservation. Pending precise results, public debate would gain from a professional judgment that terracing tends to be too expensive to justify. Contouring often pays but at interest rates too low to be profitable to farmers. The case here from society's point of view is debatable enough so that contouring might be subsidized as best in view of uncertainties.

Many observers have suggested that technical assistance be better geared to individual career capabilities and to farm and nonfarm employment possibilities. In response to exhortations along these lines, there have been pilot efforts by the Soil Conservation Service to promote economic development in local areas. An encouraging result is that some full-time assistance appears effective in catalyzing local group action. However, much of the energy has been devoted to traditional activities of the Soil Conservation Service. In short, to foster needed adjustments requires more than a call for a change of direction, both in doing economic research and in achieving reorientations of Congressmen and persons working in agencies.

G. S. TOLLEY

University of Chicago

Capital Formation in Indian Agriculture. By TARA SHUKLA. Bombay: Vora & Co., 1965. Pp. xiv, 261. \$6.00.

This study brings together in highly useful form information which shows for India as a whole, and for eight selected regions, the growth of stock or inventory of five major categories of durable assets used in farming between 1920 and 1960. In addition to the estimates of growth for the respective inventories of farm land, buildings, irrigation facilities, work animals and implements, the study makes analytical use of parallel data covering the growth of farm labor and output. The entire work has benefited from the carefully prepared analytical frame of reference that appears in Part I and which has guided the author at every crucial stage of the inquiry.

Compilation of the various series which show capital growth over four decades in some detail and on a regional basis, was a formidable undertaking, in view of the well-known problems and frustrations which beset compilers of comparable data over so long a period. In a chapter devoted to sources, and to shortcomings of data and their adjustment, the author reveals the nature and scope of the statistical problems which confronted her when she attempted to measure capital formation. That this task of assembling and adjusting original data was carefully and skillfully done will, I think, be widely recognized. Until fuller basic information is available in the reports of government agen-

cies and other fact-compiling bodies it seems unlikely that more trustworthy measures of capital growth in Indian agriculture will be produced. For this accomplishment alone the study deserves acclaim.

The growth of inventories portrayed in this study makes it clear that some net investment occurred in Indian agriculture during the 40-year span which ended in 1960, but the increases in durable capital assets which reflect it averaged only about one per cent per annum. This was barely enough to provide even the traditional, relatively inefficient implements to the ever expanding supply of farm labor, and it barely kept the capital-labor ratio from declining. Certainly it provided little with which Indian agriculture could mount a technological advance!

Small though the increase in farm assets was, it may come as a surprise that, except for funds which government had invested in irrigation and land reclamation projects (which before 1950 amounted to less than three per cent of total gross agricultural capital formation), the savings which made possible the growth of agricultural capital came mainly from the income of Indian farmers themselves. That capital from this source was obtained only as a result of considerable privation will hardly be doubted. The surprisingly strong motivation to save seems to have been associated with the inexorable growth of farm labor, and with the imperative need of farmers to equip the additional workers with at least traditional rude forms of capital. So, the relentless growth of the labor supply, and the low substitutability of labor for capital, have been the forces, more than any others, which determined the rate of capital formation in Indian agriculture. Moreover, the forms which the new capital assets have taken were greatly influenced by the source of the savings. Plagued by very low incomes and a relentless need to equip additional workers, farmers generally have been reluctant to invest their meager savings in anything but the traditional types of capital. So much is this so that Dr. Shukla reports evidence of "excess capacity" for some of the traditional forms of capital. There is, however, also evidence that farmers in India may relax a little this ultracautious approach to investment in periods of rising incomes, or when prospects for prices or crops are especially bright. Thus traditional types of capital like bullocks and wooden plows continue heavily to dominate the Indian farmer's holdings, despite recent impressive percentage gains of nontraditional types. Such high percentage gains—687 for tractors and 939 for iron plows—made in the quarter century before 1960, have had small influence on the composition of farm assets so far because they were measured from very small bases.

Still, these high percentage increases of nontraditional types of capital herald the beginnings of improvement in methods of cultivation. Further evidence that some slight improvement has occurred since World War II is found in the comparison of the share of gross investment in farm implements which was directed to the nontraditional, or technology-improving, types. In a five-year period ending in 1946 nontraditional implements (iron plows, sugar cane crushers, electric pumps, oil engines and tractors) accounted for twelve per cent of the gross investment in implements. Fifteen years later, in a similar period, the nontraditional types accounted for thirty-nine per cent. But it must

be reiterated that despite these encouraging indications of change, the great mass of capital formed in recent decades has continued to be along traditional lines—bullocks, wooden plows and carts. It is significant that the capital-product ratio began to decline only after 1950.

One of India's basic needs is for substantial and continued improvement in farm technology. A mild improvement occurred during the 1950's in connection with efforts to plan the economy, to alter the structure of agriculture by land reforms, and to reform credit institutions and market organization. Above all farm technology was improved by the establishment of extension services and community development projects. This stirring on many fronts to improve the methods of production was accompanied by capital formation more active than at any other period within the 40 year survey.

India's experience during the 1950's seems to indicate that, in an underdeveloped country, technological improvement, broadly defined, is a more potent activator of the saving-investment process than high incomes. Dr. Shukla suggests that "probably one explanation of the low rate of investment is the lack of technological improvement over much of the period we studied." Cause and effect become somewhat blurred here. There is much in this study which rightly suggests that poverty of ideas and lack of technical knowledge are not the least among the deficiencies which account for low productivity in underdeveloped countries.

Labor Economics

Manpower Planning in a Free Society. By RICHARD A. LESTER. Princeton: Princeton University Press, 1966. Pp. xiv, 227. \$5.00.

The Economics of Manpower Planning. Edited by M. R. SINHA. Bombay: Indian Institute of Asian Studies, 1965. Pp. xv, 194. \$4.00.

Is it conceivable and technically feasible to "plan" allocation and pricing of resources in a given sector while the whole system remains predominantly a "free" (unplanned) economy? This is one of the fundamental questions that arise from *Manpower Planning in a Free Society*, a "think piece" as its author calls it. This reader's reaction to the question is that "planning" in the context of the book is needlessly provocative. "Labor market policy" would be a neutral and more fitting expression for the kind of public measures proposed by the author. The need for "manpower planning," in this book, arises from widespread and entrenched imperfections in labor markets that result in wasteful redundancies of certain human resources and acute shortages of others.

If "planning" is only a sales word, Professor Lester's analysis of labor-market imperfections and of the lack of fit between the formal system of education and the economy's occupational requirements is extremely illuminating. Of particular importance is his analysis of much neglected imperfections on the

demand side of the labor market (Ch. 2 and 5). Many firms seem to entertain economically irrational desires and values. They tend to prize formal education for its own sake with little regard to other equally important indicators of skill and ability. The obsession with formal education has led to an escalation of hiring standards far beyond the basic requirements of job performance and to personnel policies that tend to dissociate the employees from labor markets. Seniority rights, fringe benefits, and welfare facilities further reduce inter-firm labor mobility. In addition, some firms discriminate against disadvantaged workers and members of minority groups for no valid economic reasons. Under the circumstances, employment does not respond to wages in the manner expected from the theoretical wage-employment relationship in which wages serve as inducements to mobility.

Imperfections on the supply side of the labor market are already well known in the literature and major findings are summarized in Chapter 6. Taken as a whole, labor market imperfections described and analyzed in this book do appear formidable and generate a sense of crisis for the urgency of a rational labor market policy. The author's references to the successes of various measures in Western Europe also make it clear that much of the waste of human resources resulting from market imperfections in the United States is wholly unnecessary. Lester thus proposes an Employment Service as a central instrument of his manpower "planning," though it is to be an institution restructured on a radically different basis from the existing institution (Ch. 3).

In other chapters, the author pleads for more research in the benefit-cost analysis of various manpower measures than has hitherto been undertaken (Ch. 7) and evaluates the contributions of research results toward effective manpower utilization (Ch. 8). His policy proposals, summarized in the concluding chapter, include a reorganized Employment Service, improvements in career counselling in high schools, a vocational training network, employment opportunities for disadvantaged workers, governmental guidelines for labor mobility, and benefit-cost analysis of manpower measures (Ch. 9). An appendix reproducing the "Manpower Development and Training Act of 1962" and an index complete the book.

Economics of Manpower Planning is a collection of seven articles that previously appeared in the *International Labor Review*. The common theme of these papers is how to fill the skill requirements of rapid economic development in underdeveloped countries. Thus, "manpower planning" takes on a different, and quite specific, meaning in this context. Manpower planning means planned increase in the supply of skills that require long periods of training whose absence create bottlenecks of planned economic development.

The most concise statement of the operational principle of manpower planning in underdeveloped countries is made by Michael Debeauvais in his opening essay, "Manpower Planning in Developing Countries." He feels that until more sophisticated calculations can be made of skill requirements, "manpower planning is restricted to the more modest aim of estimating the minimum, rather than optimum, resources to be directed to training purposes in order to safeguard economic planning targets." This means, according to Debeauvais, "deducing manpower requirements at the different levels of skill in the light of

production aims, and then drawing up the corresponding training programs. In this way an attempt is made to harmonize or, if possible, integrate economic planning, manpower planning, and educational planning." Debeauvais and others add some insights and variations to this basic principle.

The other six articles are: "The Interdependence of High Level Manpower Planning and Economic Planning" by F. Paukert, "The Labour Market and the Manpower Forecaster: Some Problems" by John Vaizey, "The Economics of Manpower Forecasting" by R. G. Hollister, "Long Term Planning of Employment in the Hungarian People's Republic" by Janos Timar, "Manpower Planning in the Restructuring of Education" by Anver Hovne, and "Manpower Policy in Japan" by Saburo Okita.

Hollister's article is a world apart from the others. Much to the delight of academic economists, it is theoretical and rigorous. Hollister explores the relationship between skill mix and product mix at different levels of national income in order to evaluate the success or failure of forecasting future skill requirements. Success is assured only under stringent conditions, i.e., constant skill coefficients and accurate knowledge of future product mix. This conclusion is enriched by considerations of major variations in the elasticity of substitution between different skills or between skill and capital. However, empirical testing of various hypotheses that follow from Hollister's analysis is fraught with great difficulties. Even the best empirical studies of changes in labor input that existed at the time of Hollister's writing (studies by Chenery, Fabricant, Komiya, and some others) fell far short of the requirements of his model.

In view of the complexity of factors that shape the course of skill mix in economic development as analyzed by Hollister, the practical propositions and strategies made by other authors in this book do sound unbelievably audacious. But this is the difference between the world of administrators and that of academic economists. Administrators often have to make decisions on the basis of insufficient evidence and analysis. If their propositions and actions broadly agree with academic analysis as exemplified by the articles in this book, they are justified for administrative efficiency.

KOJI TAIRA

Stanford University

The Urbanization of Japanese Labor, 1868-1955. By THOMAS O. WILKINSON. Amherst: University of Massachusetts Press, 1965. Pp. xvi, 243. \$6.00.

Mr. Wilkinson, who teaches sociology at the University of Massachusetts, has written an uneven book. When his analysis concentrates on Japanese urban demography (Chapters 5-10) the results are most interesting and informative. But when he attempts to place the demographic developments in historical, economic, and comparative perspective, the outcome is far less satisfactory.

The book deals with three broad questions: (1) How urban has Japan been throughout her modern period and what have been the rates of change of urbanization? (2) What are the demographic and ecological traits of Japan's urbanizing population and specifically her employed population? (3) What

are the significant parallels and contrasts between Japanese urbanization and that of the West? Questions (1) and (2) are well handled in a set of chapters on demographic characteristics of the urban population, a functional classification of Japanese cities, urban growth and demographic differentials by functional classification, and a particularly valuable chapter on metropolitan development in Japan. Wilkinson concludes that "In terms of the universals of the urbanization process, Japanese experience conforms to the theoretical model" (p. 205) which stresses the shift from agriculture to industry, more extensive division of labor, and the development of metropolitan complexes. He also underlines some unique elements in the Japanese urban-industrial transition: the role of government, "the penetration of agricultural activities into the administratively defined urban population's labor force [showing] the narrowness of the line between urban and rural labor force differentiation" (p. 207), and the continuing social and economic role of the traditional Japanese familial unit in the city.

Throughout the book, but especially in Chapter 2 on preindustrial urbanization, there are allusions to Japanese economic history. Many of these are inaccurate or vague. For example, Wilkinson speaks of "The relative stability of Japan's total population . . . during the Tokugawa Period. . . ." (p. 19). This period lasted from 1603 to 1867, and most informed scholars believe that the period of stability lasted only from the 1720's to perhaps the 1840's.¹ On the same page we read that ". . . the Kanto Plain, containing Edo (Tokyo) is by far the largest and most productive . . ." agricultural area in Japan during the rule of the *shogunate*. This must be false on two counts. First, the Tosan region produced a larger total agricultural output.² However, if by productive we are meant to infer something concerning land productivity, it is also well known that the yields in the Kanto Plain were below those of the southwest.³ Nor is it correct to say that "the practice of *sankin kotai* or alternate residence instituted by the *shogun* required that the lord spend a specified period of each year in residence in Edo" (p. 21). The period of residence varied, but generally it was alternate years. Readers may also be surprised by the statement that "landlords were little concerned with agricultural productivity" (p. 58) when applied to the Meiji Period.

Equally questionable are some of the more economic statements and conclusions. Two examples will suffice. Take the following about the period 1908-20: "Industrialization based largely upon a narrow export production, i.e. textiles, and the exploitation of limited mineral resources had almost reached a plateau" (p. 47). Yet, in 1913-17, the export-output ratios for cotton fabrics were 24.2 per cent, and for cotton yarn 30.1 per cent, at a time when these industries were growing rapidly.⁴ Total population was about 55 million, and Japanese industrialization certainly had a more solid base than narrow export production. In another place (p. 199) the author distinguishes two basically

¹ E.g. Irene B. Taeuber, *The Population of Japan*, Princeton 1958, pp. 20 ff.

² T. C. Smith, *The Agrarian Origins of Modern Japan*, Stanford 1959, p. 72.

³ Cf. T. Ogura, ed., *Agricultural Development in Modern Japan*, Tokyo, Japan FAO Association, 1963, Ch. 24.

⁴ M. Shinohara, *Growth and Cycles in the Japanese Economy*, Tokyo 1962, p. 48.

dissimilar productive systems in Japan currently and historically: the strategic industries—"shipbuilding, chemicals, armaments, and the like"—having since their beginning utilized advanced industrial technology, and production of goods for home consumption which is largely in the hands of household-handicraft units. Many scholars have used two-sector models in approaching the Japanese economy, but this version makes little sense. If we talk about modern industries, how can they be confined to "strategic" manufacturing? And don't the modern industries cater to the home market? Aren't the household-handicraft units engaged in exporting? Wilkinson even has his household-handicraft sector engaging in *subsistence* production, and that is pretty hard to imagine except in most unusual circumstances.

Finally, a word or two about comparative analysis, as used by the author. At many places in the book comparisons are made with "the West," but just exactly what this concept means or why it is the proper comparative standard for Japan is not explained. Frequently the West seems to mean Great Britain and France, and this creates problems in the form of artificial contrasts. A meaningful comparison of Japanese and European urbanization must, it seems to me, recognize the distinction between pioneer industrializers and follower countries. Only in this fashion can we make intelligent analogies. By way of illustration, let us look at the following statement: "The Industrial Revolution came to Western Europe at the culmination of a long period of revolutionary pressure from below, from an urban-based merchant class clamoring for destruction of the old social order and creation of a new one in which new institutions generated in an urban, commercial context could flourish" (p. 32). Wilkinson points out that it was not this way in Japan, and I agree. Even if this description fits Britain and France—and I have my doubts—one could still ask: so what? The industrial revolution did not come to Germany and Russia after a long period of revolutionary pressure from below, and that may be much more relevant in trying to generalize Japan's experience.

All in all, I would sum up this way: very valuable information on Japanese urbanization between 1868 and 1955 with, however, an interpretation of the results not up to the level of the demographic work.

HENRY ROSOVSKY

Harvard University

Strategies for the Displaced Worker. By GEORGE P. SHULTZ AND ARNOLD R. WEBER. New York: Harper & Row, 1966. Pp. ix, 221. \$4.95.

Automation and its concomitant evil, the displacement of labor, are the problems to which this work is directed. Endeavors to find similar employment for the labor so displaced, or, alternatively, to retrain and place such labor elsewhere are the main topics under discussion. The book also deals with the problem of financial hardship endured by a worker during the transitional period, as well as the services rendered to displaced workers by private and public agencies.

This is a lucid, detailed, straightforward, and well-written interim report of a novel attempt in the meatpacking industry by Armour & Company and two labor unions, the Amalgamated Meat Cutters and Butcher Workmen of North

America, and the United Packinghouse Food and Allied Workers, to solve the problem of large-scale labor displacement due to mechanization. The nature of the problem, and the manner in which labor and management dealt with it should be of interest to everyone, but most of all to those who are likely to be exposed to a similarly challenging situation. This work is an indispensable guide to such individuals insofar as it reveals the problems and pitfalls which are sure to attend any attempt to solve the problem of labor displacement.

In the fifteen years ending in mid-1965, twenty-one Armour plants employing about 14,000 workers had borne witness to the pervasive reorganization of the meatpacking industry (p. 6). Armour & Company agreed with the unions (which negotiate jointly) to the formation on September 1, 1959 of an Automation Fund to be administered by a committee of nine. Four representatives were from the company; four were from the unions. The impartial chairman was Professor Clark Kerr who wrote the *Foreword* to this report. In 1961, George P. Shultz, dean of the Graduate School of Business, University of Chicago, and co-author of this book, was made co-chairman. Professor Arnold R. Weber, also of the University of Chicago and co-author, worked in behalf of the committee. The functions of the committee as described in the 1961 Agreement (pp. 203-4) are: "to utilize the fund for the purpose of studying the problems resulting from the modernization program and making recommendations for their solution. . . ."

Armour & Company contributed \$500,000 to the Fund, \$140,000 of which still remained by the summer of 1965. The work of the committee was mainly concerned with labor displacement after the formation of the AFC and particularly with the closure of plants in Oklahoma City, Oklahoma; Fort Worth, Texas; Sioux City, Iowa; and Kansas City, Missouri. The problem facing the committee was further complicated by the fact that the skills of workers in the meatpacking industry are not transferable to other industries, that the median age of the workers ranged from 45 to 48, that most of them did not go beyond eighth grade in school and that their number included many Negroes and Latin Americans.

Chapter 2 contains a detailed and comprehensive account of the various measures for dealing with the effects of automation on the labor force which may be contained in a collective bargaining agreement. The next chapter discusses the sharing of job opportunities through a system of interplant transfers. Chapter 4 discusses at some length the role of financial cushions, especially severance pay and retirement income. Statistical tables are provided here. Chapter 5 discusses the role of the AFC in the placement campaigns. Of significance to future joint committees is the endeavor of the committee to expand the range of its placement activities by visiting prospective employers. "The response to these visits ranged from cordiality to outright hostility . . ." (p. 111). The longest and most informative part of the book is the sixth chapter which deals with experiments in retraining.

It is chimerical to hope that the incubus of unemployment due to automation will disappear without conscious attempts to provide for such unavoidable and even desirable eventualities. Chapter 7 is, therefore, devoted to a discussion of the aid which may be given by private agencies and by the federal

government under various Acts to those communities which are endeavoring to cope with a major displacement of labor. The last chapter of this edifying work gives a brief appraisal of the committee's endeavors and concludes with some valuable recommendations for labor market administrators. For those interested in pursuing this study in even greater detail, Appendix C contains a list of the publications arising out of the work of the AFC.

The workers assisted by the Automation Fund Committee, in this novel and highly laudable experiment, were small in number. Nevertheless, this report highlights many problems of certain future recurrence in such situations and so provides a basis for future policy. In this small project, the qualifications of the displaced workers were such as to render their re-employment exceedingly difficult. One wonders, therefore, if labor displaced in the future by the introduction of the techniques of "operations research" and "heuristic programming" will be absorbed with less difficulty. This study emphasizes the need for continuous cooperation between the communities involved and private and public agencies; it also foretells the increasing influence of the federal government in these affairs. Although not in every sense a complete success, the AFC, nevertheless—to use one of the authors' bromides—could not be expected to make a "silk purse out of a sow's ear."

JOHN C. O'BRIEN

Fresno State College

Labor Relations and Collective Bargaining. By BEVARS D. MABRY. New York: Ronald Press, 1966. Pp. vii, 475. \$7.50; Cases, \$3.00.

This is a relatively small, well-written textbook prepared for a one-semester course in collective bargaining. It assumes that the student has already had some training in labor economics. Moreover, since a large part of the book requires a good grasp of microeconomic and macroeconomic theory, the use of this text in its entirety is limited to graduate courses in economics or undergraduate students who have had work in price theory and aggregate economics.

The volume is divided into four parts. Part I, which consists of seven chapters, comprises nearly two-fifths of the book. It deals with the nature of labor relations and the roles of the participants. The author develops the idea that efforts by management and labor to achieve their respective goals sometimes leads to industrial conflict. The roles of workers, unions, and management are looked at from an interdisciplinary approach, particular emphasis being placed on sociological and psychological elements. The worker is considered within the framework of class structure and in terms of his attempt to achieve job security. The author suggests that it is logical to include professional and occupational associations (e.g., doctors, teachers) among labor organizations. The union is examined in connection with its structural and leadership problems. The relationship of the union to its membership, management, and the government is discussed. Then the changing role of management during the past few decades is indicated. Three chapters are devoted to a straightforward and factual presentation of federal and state legislation bearing on labor relations. The material relating to the states, however, is excessively detailed.

Part II, which has five chapters, represents the major *raison d'être* for the text. The theory of collective bargaining is explored with the basic tools of economic analysis. After expounding the customary theory of collective bargaining—a case of bilateral monopoly and the consequent indeterminacy of the wage settlement—the author sets forth his own complex theory based on concepts of the net gains of the parties. The less developed bargaining models worked out by Neil W. Chamberlain, Jan Pen, and Carl Stevens are discussed and compared. Two chapters are devoted to the economic effects of bargaining. The theoretical implications of the effects of increases in wages on the position of the firm and the economy are delineated. Empirical research and data in these areas are carefully reviewed to determine their relevance and consistency. The attempt to show the linkage between theory and empirical studies is particularly valuable for students.

The last two sections of the book are primarily descriptive. Part III contains three chapters on the techniques of collective bargaining. These include a chapter on the strategy and tactics of negotiations that might serve as a manual for participants in the process, another on the content of the contract, and the third on administering the agreement. Part IV on labor disputes includes four chapters. The first, dealing with the weapons available to the disputants, needs strengthening. The relative effectiveness of the weapons is not indicated, nor are they all included (e.g., whipsawing). The next two chapters cover the procedures used in emergency disputes by the state and federal governments and mediation processes. The final chapter is an unduly lengthy and general discussion of ethics, containing only a few remarks relevant to labor relations.

Each chapter ends with a conclusion. This section ordinarily summarizes the material in the chapter, although regrettably in a number of cases new facts and ideas are introduced for the first time. This is especially true in those chapters dealing with state laws, such as 7 and 17. Every chapter is followed by a group of approximately eight discussion questions and a short selected bibliography of books and government documents.

The book is written at several distinct levels. Five chapters (8 through 12) can best be understood by students well versed in economic theory; eight chapters (5-7 and 14-18) are basically descriptive; five chapters (1-4 and 19) use an interdisciplinary analysis; and one chapter (13) seems more suited as a set of reference materials for negotiators than for students using a text in collective bargaining. For those students not well trained in economics, only the first four chapters of the book are likely to be appropriate; the material in the remainder is either too difficult or more fully discussed in many of the basic texts on labor economics.

The book will be useful in many advanced courses in labor economics or collective bargaining. Nevertheless, it requires some supplementation to cover the field of labor relations and collective bargaining. Despite its 1966 publication date, the statistical material rarely goes beyond 1963. A variety of relevant and important subjects are omitted or inadequately discussed, including the special problems involved in collective bargaining for the very large group of government employees, the impact of Title VII of the Civil Rights Act of

1964 (Equal Employment Opportunity Act) as it affects admission practices of unions, and the meaning and importance of the bargaining unit and its relation to the union. Recent and current bargaining issues between management and unions, such as tripartite bargaining and growth in fringe benefits of different kinds, are not included.

The author has also written a brief companion book to the text, consisting of twenty-four actual cases involving a variety of labor problems. Each case is followed by a series of discussion questions.

ROBERT D. LEITER

City College of the City University of New York

The Measurement and Interpretation of Job Vacancies. NBER Conference Report. New York and London: Nat. Bur. of Econ. Research, 1966. Pp. ix, 593. \$12.50.

The papers appearing in this NBER volume were given at a conference designed to present a "state of the arts" picture of a statistic which has evoked considerable interest in recent years—job vacancies. This interest derives from the fact that a measure of unfilled jobs is necessary in obtaining a complete estimate of labor demand. The material is organized around four basic themes. Part I considers some of the theoretical and operational uses to which job vacancy data may be put. The experiences with this information in several foreign countries are treated in Part II. In Part III aspects of several recent surveys (some still in process) undertaken in the United States are evaluated, and in Part IV three possible alternatives to job vacancy data are evaluated.

While the central theme of this volume is a single statistic, in treating it many of the papers deal in considerable detail with the overall functioning of labor markets. Thus, as has been the case with several recent NBER conference volumes, this publication will be of interest and use to all students of labor economics—both theoretical and institutional. For example: Dunlop outlines a theory of labor hiring which places considerable emphasis on the "internal labor market," that is, movement up and down the skill ladder within the firm. A prevalence of this kind of market limits the usefulness of job vacancy information since, in the extreme, there is only one "port of entry" for the unemployed—at the low skill job. It is interesting to note the similarity between the theoretical scheme of John Dunlop and the *Nenkoh* system (lifetime commitment) in Japan, as described in the paper by G. Somers and M. Tsuda. The latter suggest that under the pressure of very tight labor-market conditions, the increasing premium placed on labor mobility has tended to dilute the *Nenkoh* system. The Japanese experience suggests that Dunlop's model should not be adopted as a general description of the U. S. labor market. The fine paper by C. Holt and M. David presents an exploratory general demand-supply model of the labor market which yields a wealth of empirical implications, and should provide many students food for thought and research. Of particular interest will be the way in which the "Phillips hypothesis" falls out of their model. In much of the published empirical work on the wage-unemployment relationship, the theoretical basis has been either omitted or presented without much rigor.

In addition to the many theoretical insights contained in these conference proceedings, several institutional aspects of the labor market are treated competently. Among these are the private employment agency and the temporary help industry. Although these two institutions seem to offer little in the way of substitute information on job vacancies, the authors have provided a useful service in simply describing and analyzing some aspects of these infrequently treated areas.

On the major questions of the usefulness and feasibility of collecting job vacancy statistics, a reading of this volume raises several troublesome issues. It is not at all clear that the same set of job vacancy statistics can be utilized optimally for both employment service activity and aggregate economic analysis. The former purpose requires a fairly detailed breakdown in terms of job content and location, while the information necessary to implement the Holt-David type model need not be nearly so detailed. A more important distinction on anticipated vacancies would seem to be highly relevant to the employment service officer concerned with educational policies and advising. Should temporary jobs be included in the vacancy list? The answer would be yes as far as employment service needs are concerned. From the point of view of aggregative analysis, however, it appears that the notion of a job vacancy is every bit as troublesome as that of its counterpart on the supply side, the unemployed worker.

Even if satisfactory definitions for both purposes could be agreed upon, there would still remain the problem of obtaining the information from employers. The general tone of the papers presented in Part III—"Job Vacancy Surveys in the United States"—is cautiously optimistic on this point. However, several discussants do not share this optimism. (The outspoken dissent of some of the discussants enlivens this volume a good bit.) Differences in employer hiring policies, hoarding of skilled workers, employer pessimism or optimism concerning future availability of labor are some of the factors mentioned in casting doubt on the ability to gather meaningful estimates of job vacancies. The fact that wage rates are not attached to the vacancy estimates thus far obtained presents an additional problem of interpretation.

The general conclusions obtained in Part II, dealing with foreign experiences, cause this reviewer, also, to view somewhat skeptically the reliability and usefulness of job vacancies as a major statistic in our present manpower program. An economy operating with unemployment close to 4 per cent is not apt to create the pressing need for detailed job vacancy information, the kind of information which would be so useful under conditions of very tight labor markets. It is not just coincidence that the demand for job vacancy data arose during the recent structuralist-aggregate demand controversy. Since this controversy is subsiding somewhat, it would be well to reconsider the need for an additional aggregate statistic—particularly since the opportunity cost of obtaining this information is greater than zero.

Poverty in America. Edited by LOUIS A. FERMAN, JOYCE L. KORNBLUH, AND ALAN HABER. Ann Arbor: University of Michigan Press, 1965. Pp. xxv, 532. \$9.00.

Poverty in America. Edited by MARGARET S. GORDON. Proceedings of a National Conference held at the University of California, Berkeley, February 26-28, 1965. San Francisco, California: Chandler Publishing Company, 1965. Pp. xxiv, 465. \$5.00; paper \$2.50.

So many books on poverty have appeared in the last couple of years that the publishers have run out of titles. Here are two substantial compendia with the same title, *Poverty in America*.

The Ferman book is an anthology, containing more than forty recent contributions to the literature of poverty, culled from books, magazines, and scholarly journals. It includes the now-classic *New Yorker* article by Dwight Macdonald, "Our Invisible Poor," Mollie Orshansky's statistical tour de force, "Counting the Poor," a fascinating article by Hylan Lewis, "Child Rearing in Low-Income Families," the pronouncements of the Ad Hoc Committee on the Triple Revolution, and a potpourri of other items. There is a brief introduction by Michael Harrington, as well as several bits of commentary from the editors.

This reviewer found the editorial comments far more irritating than enlightening. Ferman and his co-editors apparently hold a conspiracy view of poverty (sick society, power elite, the rich conspiring to profit from the misery of the poor, and so forth). They take an alarmist view of automation, and have no fear of the undocumented assertion. Their selection of articles, however, is excellent—balanced, comprehensive, and interesting.

The tone of the Gordon book is far more restrained. The only editorial comment is a lucid foreword by Lloyd Ulman which points out, among other things, that most economists view technological change as "a boon rather than a bugbear." The book consists of thirty papers presented at a conference on poverty held at Berkeley in 1965. It was a better-than-average conference and most of the contributions are worth reading. The professional economist will find more to chew on here than in the Ferman book (especially in Hyman P. Minsky's article on "The Role of Employment Policy," and Fritz Machlup's "Strategies in the War on Poverty"). The general reader, however, might get more ideas from the Ferman collection.

The spectrum of views represented in the two collections is actually quite similar and some of the poverty regulars (Robert Lampman, Sar Levitan, Frank Reissman, Michael Harrington) are represented in both. Taken together, these two books provide a good survey of what America academicians and government officials are thinking and writing about poverty and how to eliminate it. What does it all add up to? Is there a consensus—either on cause or cure?

We have clearly amassed a great many statistics about the poor. We have

detailed counts of people falling below a "poverty line" defined in terms of income and family size. We know how many of the poor are black and white, old and young, rural and urban, employed and unemployed. We know something about how the numbers and characteristics of the poor change over time given various methods of redefining the poverty line. However, judging from the evidence presented here, we know almost nothing about specific individuals and families who fall into poverty or move out of it. How many of those who were poor five years ago are still poor and what happened to the rest? Our statistics do not tell us. The persistent moan of the social statistician—too many cross-sections, no longitudinal studies—echoes through both collections.

Perhaps surprisingly, the books reflect little disagreement on public policy to reduce poverty, only differences of priority or emphasis. Minsky and others would put fiscal policy to ensure full employment at the top of their list. Frederick Harbison and others emphasize training and human investment programs. But everybody really wants both. Even the prophets of the Triple Revolution—for all their startling predictions—are in favor of education, public works, and other less-than-startling public policies.

The reader of these volumes is also impressed by the number and variety of public programs to combat poverty which are already on the books. He is provided with some descriptions of these programs and with a few poignant examples of their failures. The best-written article in the Ferman book is Mary Wright's, "The Dusty Outskirts of Hope," which describes the experiences of a proud, shy man seeking help in a busy, over-organized welfare office. It is followed by Charles Lebeaux's "Life on ADC: Budgets of Despair." There are no descriptions of successes, no analyses of programs that have been effective in moving people out of poverty. We know that poverty is declining, albeit slowly. We have a variety of public programs to hasten that decline. But we lack any real analysis of the effectiveness of these programs on which to base decisions about future emphasis in public policy. These books reflect this lack of analysis.

ALICE M. RIVLIN

Department of Health, Education, and Welfare

Poverty Amid Affluence. Edited by LEO FISHMAN. New Haven and London: Yale University Press, 1966. Pp. xii, 246. \$6.00; paper, \$1.75.

Poverty Amid Affluence. By OSCAR ORNATI, with J. S. SWEET. New York: Twentieth Century Fund, 1966. Pp. xiii, 208. Paper, \$3.25.

Two books with precisely the same title published at the very same time are likely to be much alike. These, however, could have been very different, for one presents the results of an integrated series of research projects five years in the doing, while the other is a collection of conference papers, most of which were written, it would seem, in no more than five days. The two are, in fact, very much alike: both are comprehensive, systematic, and technically unpretentious. Their comparison yields another surprise: apparently a skillful conference convener can, undoubtedly with much luck, assemble a group of

experts who, with only slight duplication, can more competently survey an issue than a single author.

Ornati's book, as he reminds the reader whenever some utterly mundane point is to be made (which is often), reports the results of a continuing research project at the New School. The report is in four parts. The three chapters of the first Part define the poor and estimate their numbers now and in the past. In the nine chapters of Part Two, the socioeconomic attributes which characterize the poor are catalogued. Part Three is devoted to examining actual and proposed antipoverty programs. These twenty-two chapters, many of which are too long, average just under six pages each. Finally the basic data and the methodology of the study are presented in thirty-five Appendices.

The Fishman volume consists of a set of invited papers presented at West Virginia University in May, 1965. It, too, is in four parts the first of which is devoted to definitions. Selected psychological and sociological consequences of being poor are taken up in the second Part. Part Three examines three poverty related attributes of people and areas, while the concluding section is devoted to policy.

The first two chapters are far and away the best of Ornati's book. Their essence is an examination over five decades of the elevating definitions of poverty that can be derived from an enormous time series of worker family budgets. Having learned from this exercise that poverty is relative in time and place and that, by the definitions of each period, poverty in the past will afflict fewer people (and just about the same proportion of people in each period too) than if any later definition is employed persistently through time, the message is promptly forgotten for the rest of the book. All of the second and third sections proceed from the belief that poverty today is different from poverty in the past, because it is now not a general affliction but is confined to particular groups. The crucial issue to Ornati is "whether a self-professing 'open society' can tolerate, not the existence of income differentials, but the existence of income differentials on the basis of social and demographic 'classes'" (p. 124). The issue, posed this way, is as phony as an Army General opposing socialized medicine. For if poverty is always defined by contemporaries to embody a virtually fixed proportion of the lower income tail, then surely it has embraced virtually the same group (except for the immigrants) since at least 1860, although their proportions vary with the age and race profile of the nation and the business cycle. This point comes through very clearly in Oscar Handlin's useful essay in the Fishman volume. The literature on poverty is widening but not deepening and perhaps this excessive taxonomy of the poor is the reason, for as Harry Johnson put it, "preoccupation with the categories of poverty can obscure or prevent understanding of the broader economics of the poverty problem and of the economic strategy required for the war on poverty" (Fishman, p. 183).

Only a short comment on the eleven papers of the Fishman volume is feasible. They are mainly descriptive; by and large each author relied heavily on his prior publications, and since they were written to be read, they are clear and pointed. Two of the papers are especially good for their genre and both

are by Robert Lampman. When a man has written so often about "Population Change and Poverty Reduction, 1947-1975" and "Ends and Means in the War Against Poverty," the probability of a flat, stale rehash is high, but in these two essays Lampman is really in tip-top form.

Putting things in better perspective, both books have some things to recommend them, but both are highly uneven. Ornati has a good discussion of the measurement problem, and many data appendices that will be useful for undergraduate term papers. The Fishman volume has good coverage with superior articles by Handlin and Lampman, and interesting articles by Alexander and Dorothea Leighton, Theodore Schultz and Harry Johnson, the main ideas of which have already been published elsewhere. For general classroom use, most instructors will prefer one or another of the many collections of readings which are available.

EUGENE SMOLENSKY

University of Chicago

Private Pensions and Individual Saving. By GEORGE KATONA. Ann Arbor: University of Michigan Survey Research Center, 1965. Pp. v, 114. \$1.50.

This monograph may well prove to be one of the most significant research reports in many years.

Armed with the facilities of the Survey Research Center at the University of Michigan and a grant from the Social Security Administration, Dr. Katona has undertaken to test the widely held premise that the spread of collective retirement security arrangements must adversely influence individual incentive to save. He felt justified in the challenge by two theories pointing in the opposite direction: "Aspirations may grow with achievement" and "Effort is intensified the closer one is to one's goal." During 1962 and 1963 his surveyors interviewed about 5,000 family units carefully selected to represent (in age distribution, income distribution, location, occupation, and education) the entire labor force. He decided to exclude the responses where the family head was already retired or a housewife or a student or under 35 or single, or where the family income was under \$3,000, on the ground that such people's retirement expectations, if any, would be atypical. There remained a crucial group of 1,853 respondents who were found to be representative, in the above mentioned respects, of about half the labor force.

Direct questions disclosed that members of this group were overwhelmingly optimistic about retirement. They were well informed about what Social Security benefits they could expect, and the great majority were confident that their retirement incomes would be adequate to meet their needs. Many expected to continue earning some income by part-time employment or self employment after retirement. Slightly fewer than one-half were participants in private pension plans, and relatively few of these were clearly aware of any impact of their pension plan participation on their spending and saving behavior.

Recognizing that direct questions often yield inaccurate information in such sensitive areas as saving behavior and expectations, the surveyors used the in-

direct method by asking questions with no apparent bearing on the central issue which produced answers that could by analysis be made to yield the desired information with a high degree of reliability. From this information there were formulated four independent variables (participation in private pension plans, expected retirement income high in relation to current income, expected retirement income greater than expected need, expected retirement income "enough") and three dependent variables (proportion of income saved in the past year greater than 5 per cent of current income, saving "behavior," and saving "mindedness"). The complex relations between these variables were examined through cross-tabulation and through multivariate analysis by digital computer calculation of regression equations. Both methods revealed that participants in private pension plans were *greater* savers—with respect to both past saving and expected future saving—than nonparticipants.

Further analysis indicated that this conclusion was unaffected by other variables such as differences of liquid asset holding, of expenditures on consumer durables, of education, and of home ownership. In addition, analysis of the relationships between the variables by a new computer technique called the Automatic Interaction Detector Program confirmed the conclusion.

The neatness and orderliness of the project are slightly flawed by some vagueness about the concept of saving. Respondents were asked, not to subtract their consumption expenditures from their incomes, but to indicate their "discretionary saving" which was defined as "net change in various forms of deposits with banks and savings institutions as well as stocks and bonds"; that is, saving was conceived as the *application* of saved funds to increase of financial asset holdings. The saving component of life insurance premiums, however, and the repayment of debt (even on homes) were excluded on the ground that they were "contractual" and not "spontaneous"; and the definition wandered over to the *source* side in announcing that "we neglect incurrence of debt because it is usually motivated by expenditure considerations (e.g., the desire to purchase a house or durable goods) rather than by saving considerations." These imperfections do not seriously compromise the study, of course, and certainly it would be unreasonable to expect a very sophisticated concept of saving in a survey of this type.

A more fundamental reservation concerns the likelihood of change in the outlook of middle-aged people generally. At present their retirement expectations are based mainly on promises. Later on, if they actually see large numbers of their older relatives and friends enjoying comfortable and worry-free retirement, their attitudes might become significantly different. That Katona is not unaware of such possibilities is indicated by several notes of caution about drawing inferences from his central conclusion. He says at the very outset, "It will be several years before a sufficient number of people covered by private pension plans will have retired so that there will be a pronounced improvement in the standard of living of the average retired person." At another point he reminds the reader that the effectiveness of the principle that achievement raises aspirations depends on prevailing conditions. "Aspirations for higher income and for an improved standard of living are raised when people are optimistic and confident rather than pessimistic or uncertain in their view

of the future." Finally, "Circumstances may change, and habituation to pension plans may change and therefore saving behavior. The studies reported in this monograph need to be repeated later."

This reviewer would add that the present report constitutes an excellent foundation for the later studies.

Population in History: Essays in Historical Demography. Edited by D. V. GLASS AND D. E. C. EVERSLEY. Chicago: Aldine, 1965. Pp. xii, 692. \$17.50.

Historical demography, the field represented by this volume, is of interest to economists working on population, labor, and economic history, and also, currently, to growth economists for the light it may shed on demographic aspects of historical economic development. In the past two decades work in historical demography has enjoyed something of a revival. The present volume, edited by David V. Glass, a demographer-sociologist, and D. E. C. Eversley, an economic historian, provides a valuable picture of the recent evolution of this field and a cross-section of representative research approaches and results. Of the 27 contributions to the volume, seven are unabridged reprints of earlier papers; the remaining ones are either entirely new or represent revisions of work published elsewhere. The contributors are divided almost evenly between the fields represented by the two editors; there is no one who holds an economics appointment.

The title of the volume somewhat misleadingly suggests an encyclopedic scope. Actually, the primary focus in space and time, presumably reflecting the emphasis of recent research, is selected populations of Western Europe in the 18th century. Studies of small local areas are especially favored. In content the papers range from questions of sources and methodology to substantive observations on demographic experience and attempts to assess the causes and, to a very limited extent, effects of demographic change. A truly outstanding contribution is a previously unpublished piece by J. Hajnal, placing Western European marriage patterns since the Middle Ages in broad spatial and temporal perspective and speculating on their interrelations with demographic and economic phenomena. In addition to an introductory chapter by each editor, other valuable contributions include papers relating to all or parts of France by Louis Henry, Pierre Goubert, J. Bourgeois-Pichat, and J. Meuvret; Scandinavia by G. Utterström; Finland by Eino Jutikkala; Germany by W. Koellmann; and Flanders by P. Deprez. Much of this represents reports on research not previously published or available in English. Economists working in the field of economic history will recognize well-known pieces (though in a few cases slightly revised) by K. F. Helleiner, H. J. Habakkuk, K. H. Connell, J. D. Chambers, D. E. C. Eversley and T. H. Marshall, and may profit from the skeptical view taken by the editors of the recent emphasis in some of this literature on fertility increase as the main factor in increased British population growth in the 18th century. Also noteworthy, though available elsewhere, are studies of the demography of British ducal families by T. H. Hollings-

worth and of Europe's ruling families by S. Peller, and one on medical evidence related to English population changes in the 18th century by Thomas McKeown and R. G. Brown.

With regard to substantive results, the primary yield is on facts of demographic experience; attempts to relate this experience to economic and other determinants are, on the whole, much less satisfying. But the facts are tantalizing and provocative ones. Although the evidence is fragmentary, the papers rather consistently point to the conclusion that by the end of the 18th century, Western European demographic conditions were quite distinctive. As Hajnal points out, "all that is pre-industrial, including eighteenth-century [Western] Europe, is often lumped together in generalizations about 'agricultural' or 'peasant' or 'underdeveloped' societies" (p. 131). Yet it appears that compared with contemporary Eastern Europe or pre-World War II underdeveloped economies, populations in Western Europe married noticeably later and a larger percentage remained single, life expectancy was noticeably longer, and fertility lower. Was there a time in Western Europe when "peasant society" demographic conditions equivalent to those in the other areas prevailed? Perhaps the fifteenth century with regard to marriage pattern; perhaps the seventeenth with regard to mortality; the picture for fertility is obscure. In any event, it would seem that in most of this area pronounced (if uneven) changes in demographic conditions occurred well before the periods commonly associated with modern economic growth. People were living longer, with more years of adulthood free from family and childcare responsibilities. Why? What bearing did this have on the current and subsequent process of economic development? These are some of the fascinating and perplexing questions raised by these essays in historical demography, questions to which economics along with the disciplines represented in the volume should be able to make significant contributions.

NOTES

In order to provide a year-round placement service for economists, the American Economic Association in cooperation with the Chicago Professional Office of the Illinois State Employment Service has established a National Registry for Economists. Candidates are asked to fill out and return a standard application form to the Chicago office. This will be kept on file and upon request will be duplicated and submitted to prospective employers. All inquiries concerning this service should be sent directly to the National Registry for Economists, 208 South La Salle Street, Chicago, Illinois 60604.

AER MANUSCRIPTS

Announcements

The Census Bureau will publish early in October a new report, "Long-Term Economic Growth: A Statistical Compendium." This report brings together almost 400 aggregate annual economic time series, almost 800 component series, and many analytical tables and charts that are helpful in studies of economic growth.

Under the authority of the Manpower Act of 1963 as amended, the Department of Labor may enter into contracts or provide grants for the conduct of research by organizations and individuals outside the Department. The Office of Manpower Policy, Evaluation and Research provides support for the following research programs: (1) Contract research for relatively definitive projects on fundamental manpower problems; (2) Research grants of up to \$10,000 in direct costs to (a) established scholars for the exploration and development of new research approaches to manpower problems and to (b) universities for the support of promising dissertation research in the manpower field; (3) Manpower research institutional grants of up to \$75,000 a year for a period of three years to colleges and universities planning to establish or strengthen their activities in the manpower field. Detailed information on procedures for submission of research proposals is contained in the Guidelines prepared for each of these programs, copies of which may be obtained from the Director, Office of Manpower Policy, Evaluation and Research, Manpower Administration, U.S. Department of Labor, Washington, D.C. 20210.

As part of its annual meeting in San Francisco, November 1966, the Medical Care Section of the American Public Health Association had a session devoted to contributed papers on the Economics of Health and Medical Care. The session was chaired by Selma J. Mushkin. The following papers were read: "The Cost of Treatment of Specific Illnesses: Some Estimating Problems and Preliminary Findings," By Anne A. Scitovsky; "The Shapes of the Costs and Production Functions for Physician's Services by Specialty, Type of Practice and Geographic Area," by Donald E. Yett; "Comparative Costs and Alternative Institutional Arrangements in the Treatment of the Mentally Ill," by Kenneth M. McCaffree; "The High Cost of Premature Death," by Dorothy P. Rice; and "Present States of Cost Benefit Analysis in the Health Field," by Herbert E. Klarman.

The Social Science Institute, Washington University, St. Louis, announces vacancies in the Community Mental Health Research Training Program at both the postdoctoral and predoctoral levels. This program is designed to prepare social scientists for research and teaching positions involving the application of social science theory and method to problems of community mental health.

Appointments in the postdoctoral program carry a minimum stipend of \$6,000 for the nine-month academic year, plus a dependency allowance. Appointments in the predoctoral program carry a minimum stipend of \$2,000, plus tuition and dependency allowance. Appointments may be renewed each year with increased stipend. Inquiries and requests for more detailed information may be addressed to George Psathas, Program Director, Community Mental Health Research Training Program, Social Science Institute, Washington University, St. Louis, Missouri 63130. Applications for appointments for the academic year 1967-68 should be directed to the Program Director by March 1, 1967.

Deaths

Arthur Z. Arnold, professor of economics, New York University.

E. G. Smith, professor emeritus, department of marketing, College of Business Administration, University of Texas.

Perry D. Teitelbaum, Resources for the Future, July 3, 1966.

Retirements

J. Fred Bell, department of economics, University of Illinois, August 1966.

Ruth Branigan, associate professor of business management, Old Dominion College, June 1966.

Clyde M. Kahler, professor of insurance, University of Pennsylvania.

Simeon Leland, dean, College of Arts and Sciences, Northwestern University, August 1966.

Charles L. Prather, professor of finance, College of Business Administration, University of Texas.

John H. Prime, distinguished professor of finance, professor emeritus and dean emeritus, School of Commerce, New York University, August 1966.

Donald Scoles, professor of insurance and finance, California State College, Los Angeles, June 1966.

Emil G. Spitzer, International Monetary Fund, November 1965; consultant, department of economic and social affairs, United Nations, February-June 1966.

John A. White, dean and professor of accounting, College of Business Administration, University of Texas.

Visiting Foreign Scholars

Robert L. Crouch, University of Essex: visiting associate professor of economics, Northwestern University.

Michael J. Farrell, Gonville and Caius College, Cambridge: visiting professor of economics, University of California, Berkeley, 1966-67.

Norman J. Gibson, University of Manchester: visiting associate professor, University of Wisconsin.

Laurence Harris, London School of Economics and Political Science: visiting assistant professor of economics, University of California, Berkeley, 1966-67.

Werner Hildenbrand, University of Heidelberg Technische Hochschule at Karlsruhe: visiting assistant professor of economics and mathematics, University of California, Berkeley, 1966-67.

Edmond Malinvaud, Institut National de la Statistique et d'Etudes Economique, Paris: visiting professor of economics, University of California, Berkeley, 1966-67.

E. Victor Morgan, University of Manchester: visiting professor of economics and commerce, Simon Fraser University, fall 1966.

André L. Müller, University College, Durban, Republic of South Africa: visiting assistant professor of economics, Dartmouth College, fall 1966.

A. Qayum, American University in Cairo: visiting professor of economics, University of Iowa, second semester 1966-67.

John M. Samuels, University of Birmingham: visiting associate professor of economics, Purdue University.

Frans Van Winckel, University of Louvain: visiting professor of applied mathematics, Graduate School of Business, University of Chicago, winter and spring 1967.

Promotions

Dennis J. Aigner: associate professor of economics, University of Illinois.

Dean F. Berry: associate professor of industry, University of Pennsylvania.

Richard A. Bilas: associate professor of economics, University of Southern California.

Francis E. Brown: associate professor of marketing and statistics, University of Pennsylvania.

John A. Carlson: associate professor of economics, Purdue University.

Charles R. Carr: professor of economics and management, Purdue University.

Richard C. Clelland: professor of statistics and operations research, University of Pennsylvania.

John R. Cox: professor of finance, California State College, Los Angeles.

Ed F. Crim, Jr.: professor of economics, University of Oklahoma.

Jean B. Crockett: professor, department of finance, University of Pennsylvania.

Michael E. DePrano: associate professor of economics, University of Southern California.

William P. Dommermuth: associate professor of marketing, College of Business Administration, University of Texas.

John E. Elliott: professor of economics, University of Southern California.

Robert P. Fairbanks: associate professor of economics, Northern Illinois University.

Antonio Giles: specialist, Interamerican Institute of Agricultural Science, OAS, Agrarian Reform, Rio de Janeiro.

David K. Hildebrand: assistant professor of statistics, University of Pennsylvania.

Eugene C. Holshouser: professor of economics, University of Georgia.

Edgar M. Hoover: university professor, University of Pittsburgh.

Mamoru Ishikawa: assistant professor of economics, University of Pittsburgh.

Shirley B. Johnson: assistant professor of economics, Washington Square College, New York University.

Jerome B. Kernan: associate professor of marketing, College of Business Administration, University of Texas.

Charles W. King, Jr.: associate professor of industrial management, Purdue University.

Robert L. Knox: associate professor of economics, Arizona State University.

Anne O. Krueger: professor of economics, University of Minnesota.

Jürgen Ladendorf: assistant professor of production, Harvard Business School.

Mildred Levy: assistant professor of economics, College of Business Administration, University of Illinois.

Cliff L. Lloyd: associate professor of economics, Purdue University.

Samuel M. Loescher: professor of economics, Indiana University.

John J. Murphy: associate professor of economics, The Catholic University of America.

David M. O'Neill: assistant professor of economics, University of Pennsylvania.

James A. Papke: professor of economics, Purdue University.

George M. Parks: associate professor of industry, University of Pennsylvania.

W. Nelson Peach: research professor of economics, University of Oklahoma.

Richard H. Puckett: assistant professor of economics, The American University.

J. C. Ray: professor of accounting, California State College, Los Angeles.

Eldon Reiling: assistant professor of economics, Northern Illinois University.

Dean Rickenbach: associate professor of economics, Brigham Young University.

John H. Riew: associate professor of economics, Pennsylvania State University.

Jack L. Robinson: associate professor of economics, University of Oklahoma.

Richard L. Rowan: associate professor of industry, University of Pennsylvania.

John Sagan: treasurer, Ford Motor Company.

Herbert I. Schiller: professor, Bureau of Economic and Business Research, University of Illinois.

Thomas F. Schutte: assistant professor of marketing, University of Pennsylvania.

Graham K. Shaw: assistant professor of economics, Washington Square College, New York University.

Franklin Sherwood: assistant professor of economics, University of Massachusetts.

John J. Sherwood: associate professor of administrative sciences, Purdue University.

Raynard M. Sommerfeld: associate professor of accounting, College of Business Administration, University of Texas.

William H. Starbuck: associate professor of administrative sciences and economics, Purdue University.

Benjamin H. Stevens: professor, department of regional science, University of Pennsylvania.

Gene B. Tipton: professor of economics, California State College, Los Angeles.

Paul Wells: professor of economics, University of Illinois.

Thomas H. Williams: professor of accounting, College of Business Administration, University of Texas.

Julian Wolpert: associate professor, department of regional science, University of Pennsylvania.

F. O. Woodard: professor of economics, Wichita State University.

Administrative Appointments

Nathan M. Becker: dean, School of Business Administration, Pace College.

Philip W. Cartwright: dean, College of Arts and Sciences, University of Washington.

Wayne W. Clark: chairman and professor of economics, Brigham Young University.

E. Kennedy Cobb: associate dean and professor of accounting, School of Business and Economics, California State College, Los Angeles.

Eirik G. Furubotn: chairman, department of economics, State University of New York, Binghamton and Harpur College.

John M. Gersting, John Carroll University: chairman, department of economics and business administration, Birmingham-Southern College.

Thomas P. Gilroy: program director, Center for Labor and Management, University of Iowa, February 1967.

Benton E. Gup: director of research, department of economics, University of Cincinnati.

Donald W. Hill: dean, Rollins College.

Sherwood G. Huneryager: assistant dean, College of Business Administration, University of Illinois.

Finn B. Jensen: chairman, department of economics, Lehigh University.

Leonard Kent: associate dean, College of Business Administration, University of Illinois.

George Kozmetsky: dean, College of Business Administration, University of Texas.

John M. Kuhlman: chairman, department of economics, University of Missouri.

Laurence E. Leamer: chairman, division of social sciences, State University of New York, Binghamton and Harpur College.

E. E. Liebhafsky: chairman, department of economics and finance, University of Houston.

Francis B. McCormick: acting chairman, department of agricultural economics and rural sociology, Ohio State University.

Francis McIntyre: associate dean and chairman, Graduate Faculty, College of Business Administration, University of Hawaii.

Edmund A. Mennis: senior vice president and chairman, Trust Investment Committee, Republic National Bank of Dallas.

Bruce R. Morris: acting head, department of economics, University of Massachusetts.

Thomas P. Murphy, National Aeronautics and Space Administration: director and professor of public administration, University of Missouri, Kansas City.

Gerald P. Nordquist: director, department of economics graduate program, University of Iowa.

Edwin P. Reubens: executive officer of Ph.D. program in economics, City University of New York.

Henry B. Schechter: director, Office of Economic and Market Analysis, Department of Housing and Urban Development, Washington, D.C.

William E. Schlender: chairman, department of management, College of Business Administration, University of Texas.

Larry S. Sgontz: acting director, Bureau of Business and Economic Research, University of Iowa.

Howard J. Sherman: chairman and associate professor, department of economics, University of California, Riverside.

Jack W. Skeels: acting head, department of economics, Northern Illinois University.

Mervin G. Smith: assistant dean of international agriculture, Ohio State University.

Frank M. Tamagna: chairman, department of economics, The American University.

John G. Turnbull: associate dean, College of Liberal Arts, University of Minnesota.

Jack T. Turner, University of Illinois: dean, School of Business Administration, Old Dominion College.

George W. Ulseth: chairman and professor, department of accounting, Wisconsin State University.

Ralph von Gersdorff: regional adviser on social and economic development and planning in Africa, United Nations Economic Commission for Africa, Addis Adaba, Ethiopia.

Ray O. Werner: chairman, department of economics and business administration, Colorado College.

J. Earl Williams: director of the Institute of Human Resources and professor of economics, University of Houston.

D. A. Worcester: acting chairman, department of economics, University of Washington.

Appointments

Rein Abel: lecturer in accounting, Wharton School, University of Pennsylvania.

George A. Akerlof: acting assistant professor of economics, University of California, Berkeley.

Juan B. Aponte: visiting associate professor of insurance, Wharton School, University of Pennsylvania.

Julius F. Aronofsky: visiting professor of statistics, Wharton School, University of Pennsylvania.

W. Michael Bailey: instructor in economics, The American University.

Maurice Baker, Rutgers—The State University: associate professor of agricultural economics, University of Nebraska.

Nancy S. Barrett: instructor in economics, The American University.

Charles I. Barteld: assistant professor of management sciences, School of Business Administration, The American University.

Richard C. Barth: assistant professor of economics, University of Maryland.

Edward Bell: instructor in economics, Miami University.

David A. Belsley, Dartmouth College: assistant professor of economics, Boston College.

Frank Benson, University of Pennsylvania: associate professor of statistics, University of Southampton.

A. V. Berger-Voesendorf: professor of economics, Sacred Heart University, Bridgeport, Connecticut.

John A. Bergeron: associate professor of business administration, Boston University.

Lawrence A. Boland, University of Wisconsin: assistant professor, department of economics and commerce, Simon Fraser University.

Jean Bourgeois-Pichat: visiting professor of economics, Wharton School, University of Pennsylvania.

Robert D. Bowers: assistant professor of economics, Western Reserve University.

David M. Bramhall: professor elect of economics, University of Pittsburgh, fall 1967.

Keith C. Brown: assistant professor of economics, Purdue University.

Antonio Camacho: assistant professor of economics, Purdue University.

Gordon Cameron: visiting associate professor of economics, University of Pittsburgh, spring trimester, 1966-67.

Vincent Cangelosi: associate professor, department of general business, College of Business Administration, University of Texas.

Thomas F. Carroll: professor of economics, George Washington University.

Hollis B. Chenery, Harvard University: visiting professor of economics, University of California, Berkeley, winter 1966.

N. K. Choudhry: visiting associate professor of economics, Wharton School, University of Pennsylvania, spring term.

Neil C. Churchill, Carnegie Institute of Technology: visiting associate professor, Harvard Business School, 1966-67.

Norman Coates: lecturer in industry, Wharton School, University of Pennsylvania.

Stanley H. Cohn, Research Analysis Corporation: associate professor of economics, State University of New York, Binghamton and Harpur College.

John Conlisk, Rice University: assistant professor of economics, University of Wisconsin.

Arthur J. Corazzini: instructor in economics, Dartmouth College.

Arthur J. Cordell, National Commission on Food Marketing: Joel Dean Associates, New York City.

Harley Courtney: assistant professor of accounting, College of Business Administration, University of Texas.

Robert Crockett: lecturer in finance, Wharton School, University of Pennsylvania.

John M. Culbertson, University of Wisconsin: visiting professor in economics, University of California, Berkeley, 1966-67.

Anthony J. Curley: lecturer in finance, Wharton School, University of Pennsylvania.

Edgar R. Czarnecki: assistant professor and program director for labor education, Center for Labor and Management, University of Iowa.

Clarence H. Danof: professor of economics, George Washington University.

Philip Davidowitz: visiting associate professor, Harvard Business School.

Marcia Davidson, U.S. Treasury: assistant professor of economics, Boston College.

Charles M. Dehority: assistant professor of business management, Old Dominion College.

David R. Denzler: assistant professor of industrial management, Purdue University.

Gary Devino: assistant professor of agricultural economics and marketing, Rutgers—The State University.

Walter A. Dinsdale: visiting professor of finance, College of Business Administration, University of Texas.

Bagio Di Venuti, St. Louis University: professor of economics, Catholic University, Dominican Republic.

Ryszard Domanski: visiting lecturer in regional science, Wharton School, University of Pennsylvania.

John A. Domonkos, Federal Reserve Bank, Cleveland: instructor in finance, Western Reserve University.

Richard E. Dutton: visiting associate professor of management, College of Business Administration, University of Texas.

Bruce E. Edwards: associate professor of economics, Bowling Green State University.

Kenneth K. L. Fan: computer research specialist, College of Business and Social Sciences, Utah State University.

Barry C. Field: assistant professor of economics, George Washington University.

Charles Fishbaugh: assistant professor of economics, Florida State University.

Boyd L. Fjeldsted: assistant professor of economics, University of Utah.

F. Marion Fletcher: lecturer in industry, Wharton School, University of Pennsylvania.

Carter L. Franklin: lecturer in industry, Wharton School, University of Pennsylvania.

E. Bruce Fredrikson: University of Pennsylvania, appointment at Syracuse University.

William O. Freithaler: research staff, department of economics, RAND Corporation.

R. J. Freund: associate professor of economics, Texas A & M University.

Bruno Frey: visiting lecturer in economics, Wharton School, University of Pennsylvania.

Ann Friedlaender: assistant professor of economics, Boston College.

Emma L. Fundaburk: assistant professor of economics, Bowling Green State University.

Nelda Garcia: instructor in general business, College of Business Administration, University of Texas.

John L. Gardner: instructor in economics, University of Minnesota.

Charles E. Gearing: assistant professor of industrial management, Purdue University.

William F. Glueck: assistant professor of management, College of Business Administration, University of Texas.

Andrew Gold: assistant professor of economics, Miami University.

H. Scott Gordon: professor of economics, Indiana University.

Bertram Gottlieb, AFL-CIO: visiting professor, Center for Labor and Management, University of Iowa, 1966-67.

David H. Greenberg, Massachusetts Institute of Technology: research staff, logistics department, RAND Corporation.

Stephen A. Greyser, *Harvard Business Review*: assistant professor of marketing, Harvard Business School.

Irwin Gross: lecturer in marketing, Wharton School, University of Pennsylvania.

James A. Gross, Holy Cross College: assistant professor, New York State School of Industrial and Labor Relations, Cornell University.

Herbert Grubel: associate professor of finance, Wharton School, University of Pennsylvania.

Shiv K. Gupta: visiting professor of statistics, Wharton School, University of Pennsylvania.

Charles W. Hackett, Jr.: assistant professor of finance, College of Business Administration, University of Texas.

Ernest J. Hall, Jr.: associate professor of management, College of Business Administration, University of Texas.

Michael J. Hamburger, University of Pennsylvania: Federal Reserve Bank of New York.

John S. Hammond, III: instructor in managerial economics, reporting and control, Harvard Business School.

Bent Hansen: professor of economics, University of California, Berkeley.

H. O. Hartley: professor of economics, Texas A & M University.

Gerald R. Hartman: assistant professor of insurance, Wharton School, University of Pennsylvania.

Michio Hatanaka, University of Rochester: professor, Osaka University.

John M. Hatcher: assistant professor of accounting, Purdue University.

Robert H. Hayes, Stanford University: assistant professor of management, Harvard Business School.

Rolf Hayn: senior economist, Pan American Union.

Thomas Havrilesky: assistant professor of economics, University of Maryland.

Upton B. Henderson, University of Missouri: assistant professor of economics, Hiram Scott College.

J. L. Heskett, Ohio State University: associate professor of marketing and business logistics, Harvard Business School.

Sidney Hess: associate professor of statistics, Wharton School, University of Pennsylvania.

R. R. Hocking: associate professor of economics, Texas A & M University.

Thomas E. Holland: associate professor of economics, Texas A & M University.

Ann M. R. Horowitz: assistant professor of economics, Indiana University.

Donald C. Horton: associate professor of economics, Bowling Green State University.

Howard T. Hovde: distinguished visiting professor of marketing, College of Business Administration, Kent State University.

Edward Howle: lecturer in economics, Indiana University.

H. W. Huegy: visiting professor of marketing, College of Business Administration, University of Texas.

Shinichi Ichimura: visiting professor of economics, Wharton School, University of Pennsylvania.

James W. Jenkins: special instructor in economics, Brigham Young University.

Eugene Jentges: instructor in business administration, Hiram Scott College.

Gaylord A. Jentz: associate professor of general business, College of Business Administration, University of Texas

Dudley D. Johnson, University of Virginia: instructor in economics, Dartmouth College.

Howard E. Johnson: assistant professor of management, College of Business Administration, University of Texas

Mildred E. Jones: fuels economist, Tennessee Valley Authority.

Ronald D. Jones, RAND Corporation: associate professor, School of Business and Public Administration, University of Missouri, Kansas City.

Hyman Joseph: assistant professor of economics, University of Iowa.

Ralph Kaminsky: associate professor of public finance, Graduate School of Public Administration, New York University.

Edward J. Kane, Princeton: associate professor of economics, Boston College.

John W. Kendrick: professor of economics, George Washington University.

Edward R. Kittrell, University of Alberta: associate professor of economics, Northern Illinois University.

Benjamin J. Klebaner: economic adviser, Second National Bank Region of New York, New Jersey, Puerto Rico and the Virgin Islands.

Linda J. Kleiger, University of California, Los Angeles: research staff, logistics department, RAND Corporation.

Michael Klein: lecturer in economics, Indiana University.

Lennis M. Knighton: assistant professor of accounting, College of Business Administration, University of Texas.

Shou Eng Koo: associate professor of economics, College of Business Administration, University of Georgia.

Richard Kosobud, Wayne State University: visiting associate professor of economics, College of Business Administration, University of Illinois, Chicago.

John F. Kottas: lecturer in industry, Wharton School, University of Pennsylvania.

Ezra Krendel: visiting professor of statistics, Wharton School, University of Pennsylvania

Harvey A. Krow: visiting associate professor of economics, University of Pittsburgh.

Kermit D. Larson: assistant professor of accounting, College of Business Administration, University of Texas.

Prem S. Laumas, Ohio University: assistant professor of economics, Northern Illinois University.

Alton D. Law, Rutgers—The State University: assistant professor of economics, Western Maryland College.

Chung Lee: assistant professor of economics, Miami University.

James Leontiades: assistant professor of marketing, Wharton School, University of Pennsylvania.

Abba P. Lerner: professor of economics, University of California, Berkeley.

Larry G. Little: special instructor in economics, Brigham Young University.

Philip J. Lund: visiting lecturer in economics, Wharton School, University of Pennsylvania.

Craig C. Lundberg: assistant professor of industry, Wharton School, University of Pennsylvania.

Asatoshi Maeshiro: assistant professor of economics, University of Pittsburgh.

Miles Martin, University of Pennsylvania: appointment at Michigan State University.

Ferdinand J. Mathis, University of Iowa: assistant professor of economics, College of Business Administration, University of Illinois, Chicago.

S. Charles Maurice: temporary instructor in economics, College of Business Administration, University of Georgia.

Melvin L. Meer: assistant professor of economics, University of Maryland.

David I. Meiselman, U.S. Treasury Department: visiting professor of economics, University of Minnesota, spring quarter 1967.

Robert D. Mettlen: assistant professor of finance, College of Business Administration, University of Texas.

Marcel Michel: visiting lecturer in marketing, College of Business Administration, University of Texas, spring 1965-66, fall 1966-67.

Norman C. Miller: assistant professor of economics, Bowling Green State University.

Ralph E. Miller: acting assistant professor of economics, University of California, Berkeley.

J. Sayer Minas, University of Pennsylvania: appointment at University of Waterloo, Canada.

A. L. Nagar: visiting professor of economics, Wharton School, University of Pennsylvania.

Richard E. Neel, University of South Florida: director of institutional planning, Florida Technological University.

John P. Nieuwenhuysen: visiting associate professor, University of Pittsburgh, fall trimester 1966.

J. Randolph Norsworthy, University of Chicago: assistant professor of economics, College of Business Administration, University of Illinois, Chicago.

John H. Norton, University of Pennsylvania: appointment at George Washington University.

Mamoru Ogata: assistant professor of economics, Brigham Young University.

Alper Y. Orhon, Vanderbilt University: instructor in economics, Dartmouth College.

Jerry H. Padgett: assistant professor of economics, College of Business Administration, University of Georgia.

John B. Parr, assistant professor of regional science, Wharton School, University of Pennsylvania.

Charles R. Perry: lecturer in industry, Wharton School, University of Pennsylvania.

Robert F. Pethia: assistant professor of management, College of Business Administration, University of Texas.

Maurice Pfannestiel: assistant professor of economics, Wichita State University.

Edmund S. Phelps: professor of economics, Wharton School, University of Pennsylvania.

Clynn Phillips: assistant professor of economics, University of Wyoming.

George B. Pidot, Jr., Harvard University: assistant professor of economics, Dartmouth College.

Felix Pollaczek: visiting professor of statistics, Wharton School, University of Pennsylvania.

Edward C. Prescott: lecturer in economics, Wharton School, University of Pennsylvania.

Wilfred Prest: visiting professor, University of Pittsburgh, fall trimester 1966.

Charlotte Price: visiting assistant professor of economics, Vassar College.

Arthur M. Rade: financial analyst, research department, Shields & Company.

J. N. K. Rao: associate professor of economics, Texas A & M University.

Robert H. Rasche: assistant professor of economics, Wharton School, University of Pennsylvania.

Albert Rees, University of Chicago: professor of economics and public affairs, Princeton University.

Raymond L. Richman: professor of economics, University of Pittsburgh.

Myles E. Robinson, National Coal Association: professor of transportation and marketing, School of Business Administration, The American University.

C. Stevenson Rowley, Saint Cloud College: assistant professor of business administration, Whittemore School of Business and Economics, University of New Hampshire.

David S. Salsburg: assistant professor of statistics, Wharton School, University of Pennsylvania.

Phillip J. Scaletta, Jr.: associate professor of business law, Purdue University.

Stanley S. Schor, University of Pennsylvania: appointment at Temple University.

Harold M. Seeberger, St. Louis University: assigned to Pontificia Universidad Católica del Ecuador.

David Seymour: lecturer in regional science, Wharton School, University of Pennsylvania.

G. L. S. Shackle: visiting professor, University of Pittsburgh, winter trimester 1966-67.

James F. Shepherd: assistant professor of economics, Purdue University.

Donald R. Sherk, U.S. Military Academy: assistant professor of economics, Boston College.

Philip H. Siegel: assistant professor of economics, Auburn College.

Tony E. Smith: lecturer in regional science, Wharton School, University of Pennsylvania.

Daina Smits: instructor in economics, University of Minnesota.

Robert A. Solo: professor of economics and management, Graduate School of Business Administration, Michigan State University.

Frank Stafford: study director, Survey Research Center, University of Michigan.

Henry B. Steele: associate professor of economics, University of Houston.

Frank I. Stern: assistant director, Marketing Information System, New York Central System.

W. W. Stevens: visiting assistant professor of economic education, Purdue University.

Hans S. Stoll: assistant professor of finance, Wharton School, University of Pennsylvania.

Theo Suranyi-Unger, Goettingen University: professor of economics, Northern Illinois University.

Ben B. Sutton: professor of finance, University of Houston.

Akira Takayama: visiting associate professor of economics, Purdue University.

Paul J. Taubman: associate professor of economics, Wharton School, University of Pennsylvania.

Benjamin J. Taylor: assistant professor of economics, Arizona State University.

Azriel A. Teller, Johns Hopkins University: assistant professor of economics, College of Business Administration, University of Illinois, Chicago.

Rollin G. Thomas: visiting professor of economics, Bowling Green State University.

Douglas J. Tigert: assistant professor of industrial management, Purdue University.

Arthur Treadway: instructor in economics, Northwestern University.

David G. Tuerck, University of Virginia: assistant professor of economics, College of Business Administration, University of Illinois, Chicago.

Tze H. Tung: assistant professor of regional science, Wharton School, University of Pennsylvania.

Franklin D. Van Buer, University of Nigeria: assistant professor of economics, Northern Illinois University.

Terence J. Wales: lecturer in economics, Wharton School, University of Pennsylvania.

Franklin V. Walker: professor of political economy, Graduate School of Public Affairs, State University of New York, Albany.

Richard Wallace, Florida State University: assistant professor of economics, University of Missouri.

Brendan Walsh, University of Massachusetts: appointment at Tufts University.

Bernard Warner: visiting professor of statistics, Wharton School, University of Pennsylvania.

Samuel Webb: assistant professor of economics, Wichita State University.

John E. Weinrich, University of Alberta: visiting professor of economic and business enterprise, State University of New York, Binghamton and Harpur College.

Louis T. Wells, Jr.: assistant professor, Harvard Business School.

William F. Whitbeck: assistant professor of marketing, Old Dominion College.

Melvin I. White, Brooklyn College: deputy assistant secretary (for tax policy), U.S. Treasury, Washington, D.C.

Jeremy L. Wiesen: assistant professor of business law, Wharton School, University of Pennsylvania.

C. Glyn Williams, Indiana University: assistant professor of economics, Boston College.

John J. Willingham: visiting associate professor of accounting, College of Business Administration, University of Texas.

Sidney G. Winter, Jr., University of California, Berkeley: research staff, economics department, RAND Corporation.

Rufus Wixon: professor of accounting, Wharton School, University of Pennsylvania.

Richard C. Yates: assistant professor of economics, Arizona State University.

Elinor B. Yudin: lecturer in economics, New York University.

Leaves for Special Appointments

F. Gerard Adams, University of Pennsylvania: consultant on questions of forecasting for U.S. State Department, OECD, Paris, 1966-67.

Sabbah Al Haj, Bowling Green State University: visiting lecturer, American University, Beirut, 1966-68.

Jim G. Ashburne, University of Texas: professor of accounting, University of Hawaii, 1966-67.

Vladimir N. Bandera, Boston College: Fulbright professor of economics, Pavia University, Italy, 1966-67.

Raul M. Branco, University of Texas: on assignment with United Nations, 1966-67.

John S. Chipman, University of Minnesota: visiting professor, Harvard University, 1966-67.

Geoffrey P. E. Clarkson, Massachusetts Institute of Technology: visiting professor, London School of Economics and Political Science, 1966-67.

Bernard L. Codner, California State College, Los Angeles: consultant in economics, University of Parafba, Brazil, and professional staff member on the RITA project, 1966-67.

Herbert S. Denenberg, University of Pennsylvania: associate director of staff, Wisconsin Legislative Council, 1966-67.

H. Peter Gray, Wayne State University: visiting professor of economics, Thammasat University, Bangkok, 1966-67.

Peter Gregory, University of Minnesota: International Labor Organization, Switzerland, 1966-67.

Marshall Howard, University of Massachusetts: visiting professor, University of California, Berkeley, 1966-67.

Pamela Kacser, The American University: visiting lecturer in economics, Columbia University, 1966-67.

Dennis C. Mueller, Simon Fraser University: staff, Brookings Institution, 1966-68.

J. A. Nordin, Kansas State University: visiting professor of economics, University of Wisconsin, second semester 1966-67.

Kenneth W. Olm, University of Texas: visiting professor, University of New Mexico, 1966-67.

Jonas Prager, New York University: assistant professor, Bar-Ilan University and Bank of Israel, 1966-67.

Lawrence L. Schkade, University of Texas: visiting professor, Monterrey Technological Institute, 1966-67.

Please mention *THE AMERICAN ECONOMIC REVIEW* When Writing to Advertisers

New Books in Economics for Fall Classes

ECONOMICS: A GENERAL INTRODUCTION, Revised Edition

By **LOYD G. REYNOLDS**, Yale University

This new revision retains the features which made the previous edition a truly outstanding text, and at the same time about 40 percent of the material is entirely new and all has been updated. A completely revised Review Guide and Workbook, by John Arana and Richard Porter, and an Instructor's Manual by the author, accompany Economics. 985 Pages

THE CANADIAN ECONOMY: Organization and Development

By **IAN M. DRUMMOND**, University of Toronto

A supplement to Reynolds's Economics, this concise paperback serves as a beginner's guide to the Canadian economy, presents Canadian economic data, and discusses questions of Canadian economic policy. 153 Pages Paperbound

STATISTICAL METHODS IN ECONOMICS

By **HAROLD W. GUTHRIE**, University of Illinois

Directed primarily to students who have had a course in principles of economics, this book attempts to teach statistical methods within the context of economic principles and policy. A Manual of Problems to supplement the text has been prepared by the author. About 250 Pages

SELECTED ANTITRUST CASES: Landmark Decisions, Third Edition

By **IRWIN M. STELZER**, National Economic Research Associates

Consisting of a compilation of landmark judicial decisions in the field of antitrust law, this book gives students in economics, government, and business administration a clear understanding of our antitrust laws. There has been an increase in the number of cases and in coverage of dissenting opinions. About 300 Pages Paperbound

MICROECONOMIC THEORY

By **C. E. FERGUSON**, Duke University

This new book is believed to be more thorough than any comparable text. This is especially true for the theory of production with more than one variable input, the theory of general economic equilibrium, and the theory of welfare economics. 453 Pages

INTERMEDIATE ECONOMIC ANALYSIS, Fifth Edition

By **JOHN F. RUE**, University of Illinois, and
ROBERT W. CLOWER, Northwestern University

The new Fifth Edition has been substantially rewritten to raise the level of the analysis, to eliminate material now covered more adequately in principles courses than in the past, and to improve the exposition. 494 Pages
